AN
ENCYCLOPÆDIA
OF
GEOGRAPHY:

COMPRISING A
COMPLETE DESCRIPTION OF THE EARTH,
Physical, Statistical, Civil, and Political;
EXHIBITING ITS RELATION TO THE HEAVENLY BODIES,
ITS PHYSICAL STRUCTURE,
THE NATURAL HISTORY OF EACH COUNTRY,
AND THE INDUSTRY, COMMERCE, POLITICAL INSTITUTIONS,
AND CIVIL AND SOCIAL STATE
OF
ALL NATIONS.

BY HUGH MURRAY, F.R.S.E.

ASSISTED BY THE FOLLOWING GENTLEMEN, IN THEIR RESPECTIVE DEPARTMENTS OF SCIENCE:

ASTRONOMICAL AND MATHEMATICAL
GEOGRAPHY:

WILLIAM WALLACE, A.M. F.R.S.E.
PROFESSOR OF MATHEMATICS IN THE UNIVERSITY
OF EDINBURGH.

GEOLOGY AND THE DISTRIBUTION OF
MINERALS:

ROBERT JAMESON, F.R.S.E.
REGIUS PROFESSOR OF NATURAL HISTORY,
LECTURER ON MINERALOGY, ETC. IN THE UNIVERSITY
OF EDINBURGH.

BOTANY AND THE DISTRIBUTION OF
PLANTS:

W. J. HOOKER, LL.D. F.R.A. & L.S.
REGIUS PROFESSOR OF BOTANY IN THE UNIVERSITY
OF GLASGOW.

ZOOLOGY AND THE DISTRIBUTION OF
ANIMALS:

WILLIAM SWAINSON, ESQ. F.R.S.
& F.L.S. &c. &c.

ILLUSTRATED BY EIGHTY-TWO MAPS,

DRAWN BY SIDNEY HALL,

AND UPWARDS OF A THOUSAND OTHER ENGRAVINGS ON WOOD,

BY R. BRANSTON,

FROM DRAWINGS BY SWAINSON, T. LANDSEER, SOWERBY, STRUTT, &c.

REPRESENTING THE MOST REMARKABLE OBJECTS OF NATURE AND ART
IN EVERY REGION OF THE GLOBE.

LONDON:
LONGMAN, REES, ORME, BROWN, GREEN, & LONGMAN,
PATERNOSTER-ROW.
1834.

LONDON:

Printed by A. SPOTTISWOODE, New Street Square;

AND

VIZETELLY, BRANSTON & Co. Fleet Street.

P R E F A C E.

THE value and importance of the study of Geography are so obvious, and indeed so universally acknowledged, as to require little illustration. Nothing can be more interesting to man, or more gratify his thirst for knowledge, than a survey of the earth which he inhabits, peopled as it is by beings of the same nature with himself. To visit and observe foreign climes and regions is an object of general desire, and forms one of the most effectual means of enlarging and enlightening the human mind. This wish, however, unless in the case of a few individuals, can be gratified only to a very limited extent, and in none can embrace more than a small portion of the vast variety of interesting objects which the earth comprises. This necessary defect of personal observation may, however, be in a great measure supplied, by collecting the reports and narratives of those intelligent individuals who have explored and described its various regions, and forming out of these a general description of the world and its inhabitants.

Works of this class have always possessed a peculiar attraction. Even in ancient times, when the extent of the known world, and the information with respect to the inhabitants and productions of its remoter regions, were comparatively limited, the geographical descriptions of Herodotus, Strabo, Pomponius Mela, and Pliny, rank among the most valuable productions of the classic ages. But in modern times, and particularly in the present age, Geography has acquired a much more prominent place among the departments of human knowledge. The discovery of America in the fifteenth century awakened a spirit of enterprise, and a desire to explore unknown regions, that has continued to gain new strength. During the last half century more especially, the most civilised nations of Europe have been contending with each other for the glory of discovery; and there is now scarcely a shore however remote, or the interior of a continent however barbarous or difficult of access, which has not been surveyed and described. Materials have thus been provided for a much more complete, interesting, and authentic description of the earth, than could have been drawn up at any former period.

The extensive discoveries thus recently made have thrown a wonderful light on the structure and productions of the earth, and afforded large contributions to all the departments of natural history. They have also displayed man in every varied condition, from the highest refinement of civilised society, to the rudest and most abject condition of savage life. These representations are not only interesting in themselves, but throw light on the history of past ages. Communities are still found exactly similar to some of those described in the earliest records of antiquity. The

tent of the Arab sheik differs little from that which Abraham pitched on the plains of Mamre; many of the Tartar tribes are a people exactly similar to those who roamed in early ages over the plains of Scythia; and the splendid courts of Babylon and Persepolis have their representatives in the existing world. We may thus, in fact, trace back man to an earlier and ruder stage than any represented in the ancient records; for these convey only faint and fabulous notions of what mankind had been at a very early period. But the wilds of America, and the shores of the Pacific, exhibit the state of savage simplicity, which doubtless existed in Europe before the light of authentic history had begun to dawn. Hence it is that Geography, in its present extended range, not only shows man as he actually exists, but delineates, as it were, the progressive history of the species.

Besides the gratification thus afforded to a liberal curiosity, the knowledge of even the remotest regions has, through recent events, become an object of the utmost practical importance. In many of these, colonies have been founded, political relations formed, and a commercial intercourse with them opened, by the civilised nations of Europe, and particularly by Britain. Regions the most distant to which a ship can sail form integral portions of her dominion, and have their ports crowded with her vessels. There are thousands in this country who have a more intimate connection with Calcutta or Sydney, than with towns in their immediate vicinity. The manufacturer labours to supply the markets of countries, the very existence of which, fifty years ago, was unknown; the circumnavigation of the globe is now an ordinary trading voyage. The knowledge of Geography has thus become a necessary qualification for the pursuits of commerce and industry, and for much of the ordinary and current business of life. A great proportion of the youth of Britain are trained for employments in countries which lie far beyond the limits of Europe.

The same causes have, moreover, given to the knowledge of distant countries a peculiar hold on the domestic and social affections. There are few amongst us who have not a near relation, perhaps a brother or a child, residing in another hemisphere. Oceans now separate us from those to whom we are united by the tenderest ties; the objects of our affection have their abode on the banks of the Ganges, or the shores of the Pacific; and many, whose hearts are knit in the closest friendship, are divided from each other by half the earth. In this situation, a description of the place in which our friend or relative dwells, the objects which meet his eye, the society in which he mingles, must afford peculiar gratification, and soothe the mind under this painful separation.

Deeply impressed with a sense of the great extent and difficult execution of a complete geographical work, the Editor, during nearly ten years in which he has been engaged upon it, has used the utmost exertion to procure from every quarter information and aid. He has studiously collected the most recent, authentic, and accurate accounts of the extent, natural features, population, productions, industry, political constitution,

literature, religion, and social state of the various regions of the globe, with the leading details as to their districts and cities. The sciences connected with the natural history of the earth have, however, attained to such an extent and importance, that a thorough knowledge of them can only be possessed by individuals who have specially devoted themselves to one particular branch. The Editor, therefore, considered it essential to procure the co-operation of writers who had risen to acknowledged eminence in the departments of Geology and Mineralogy, Zoology and Botany. He considered that he had fully succeeded, when Professor Jameson undertook to delineate the geological structure of the globe, and the distribution of minerals over its surface; Mr. Swainson to explain the distribution of animals, and the most remarkable of those found in each particular region; and Dr. Hooker to perform the same task in regard to the vegetable kingdom. Professor Wallace has illustrated the relations of the earth as a planet, the trigonometrical surveys, the construction of maps, and other subjects connected with mathematical science. These tasks have been executed in a manner which, it is hoped, will fully support the high reputation of their respective authors. In preparing the sections relating to commerce, the editor derived much assistance from Mr. M^cCulloch's Dictionary of Commerce, and he is also indebted to that gentleman for many valuable communications. Various parts relating to remote countries have been revised by gentlemen recently returned from them, particularly Barron Field, Esq. Chief Justice of Gibraltar, some years resident in Australia. It is only justice to add, that neither exertion nor expense have been spared by the Publishers, to enable the Editor to render the work as perfect as possible.

The Maps, which are so numerous as to form a complete Atlas, have been executed from drawings by Hall; and having been carefully revised by the Editor, they will, it is hoped, be found to be accurate, and to include all the most recent discoveries. Notwithstanding the smallness of the scale, they are illustrated by the letter-press in a manner which enables them to comprise equal information with others of much larger dimensions.

The other Wood Engravings are mostly original, or have been carefully selected from the most faithful representations of the objects described; and they are executed in the best style by the eminent artists whose names appear on the title-page. They exhibit the most remarkable plants and animals, the chief cities, public buildings, natural curiosities, and picturesque scenery, with the characteristic figures and costumes of the natives, in the countries described. It is not believed that any work of this kind is similarly embellished, at least to nearly the same extent. These representations are by no means introduced for the sake of mere ornament; they will be found of the greatest utility, conveying an infinitely better idea of the objects than could be derived from the most laboured description.

*Segnius irritant animos, demissa per aures,
Quam quæ sunt oculis subjecta fidelibus.*

Notwithstanding all these efforts, it is impossible to lay this volume before the Public without the painful reflection, that, in a subject involving such an infinite number and variety of details, many of which are often very difficult to procure, not a few imperfections and even errors must inevitably occur. M. Balbi, whose exertions to collect the most recent geographical information are well known, and to whose labours the present volume is much indebted, candidly observes:— “One of the greatest obstacles to be surmounted in the composition of an elementary treatise of Geography is the want of contemporary documents. Geography is almost necessarily a compound of things which are, with things which have ceased to be. How can one be informed of all the changes that take place in the course of a few years, even in the capitals of Europe, still more in those of Asia, Africa, and America? To compose a Geography which should exhibit a complete picture of the globe at a particular period, it would be necessary to have authentic documents, all of the same date, and that a recent one; which never has been, and never can be.” As, therefore, the local knowledge of many into whose hands this work may fall will enable them to discover defects, an intimation of these, addressed to the Publishers, will be gratefully received, and employed in the correction of a future impression.

OF

G E O G R A P H Y.

INTRODUCTION.

GEOGRAPHY consists in the description and delineation of the Earth. It considers that planet in respect to its form, its connexion with other bodies in the universe, the various parts into which it is divided, their relations to each other, and the objects with which each is respectively filled. Geography indeed could not attempt a scientific analysis of all these objects, without seeking to comprehend within itself a complete circle of science. It views only their obvious and visible characters, and chiefly those features which are peculiar to each respective country and region on the face of the globe.

The great importance of this branch of knowledge must be sufficiently obvious. It embraces a vast variety of those objects which are most interesting in themselves, and with which it most concerns man to be conversant. It enables the navigator, the merchant, the military commander, to carry on their respective operations. Geography is moreover essential to the clear understanding of every branch of the history both of man and nature. The transactions of bordering states are unintelligible without a knowledge of their relative extent and position, and of the theatre on which the great events of their history are acted. Every form, both of animal and vegetable nature, is modified in the most striking manner by the climate or the country in which it is placed. Still more intimate is its relation with geology and other sciences, which investigate the materials composing the substance and crust of the earth. None of these branches of knowledge can be distinctly understood, or viewed under its proper relation and arrangement, without a previous knowledge of geography.

This important and extensive subject seems to divide itself naturally into three parts.

The *First Part* treats of the "History of Geography;" the origin and progress of the Science; and the steps by which man, who seemed fixed by nature in a local and limited position, has made himself acquainted with the immense circuit of the globe. This Part is divided into — I. Ancient Geography; — II. Geography of the Middle Ages; — III. Modern Geography.

The *Second Part* comprises the *Principles* of the Science. These are — I. *Mathematical*: those which relate to the form of the earth, its movements, its place in the Solar System, the great circles by which it is divided, the operations by which it is surveyed, and the modes in which its spherical outline can be represented on the plane surface of a map. II. *Physical*: those which treat of the substances which cover the earth's surface, the elements which compose and surround it; rock, earth, water, air, as they appear under the various forms of mountain, plain, river, sea, and present all the changing phenomena of the atmosphere. III. Geography may be considered in its relation to other objects and sciences. 1. To Zoology, or the distribution of animals over the globe. 2. To Botany, or the diffusion of vegetable productions. 3. To the human race, and the various branches into which it has been formed, considered in relation to numbers, wealth, political union, social, intellectual, and moral condition.

The *Third Part* considers Geography in detail, as it applies to the various quarters and countries into which the world is divided, the outline and extent of each, its natural features, the revolutions through which it has passed, its political constitution, the industry and wealth,

the civil and social condition of its inhabitants. The description of each country will conclude with a local and topographical survey of its districts, cities, and towns.

This Part will divide itself into five general heads:—I. Europe. II. Asia. III. Africa. IV. America. V. Australia.

An Index will be added, which, being extremely copious, and containing references to all the places mentioned in the work, will answer in a great degree the purposes of a Geographical Gazetteer.

PART I.

HISTORY OF GEOGRAPHY.

1. *The History of Geography* may be divided into three books:—I. Ancient Geography. II. Geography of the middle ages. III. Modern Geography.

BOOK I.

ANCIENT GEOGRAPHY.

2. *The Geography of the Ancients* may be considered under the heads of, I. Hebrew and Phœnician Geography; the principal features of which may be found in the Jewish Scriptures. II. Greek Geography, in its early state, before the expedition of Alexander. III. The first Alexandrian school formed by Eratosthenes. IV. The Roman school, formed chiefly by Mela and Pliny. V. The second Alexandrian school formed by Ptolemy.

CHAP. I.

HEBREW AND PHŒNICIAN GEOGRAPHY.

3. *The Sacred Records*, in addition to their higher claims on the attention of mankind, possess the important secondary advantage, that they enable us to trace human existence, and the forms of society, back to a much earlier period than the information derived from any other source. They were long anterior in this respect to the classic story of Greece and Rome; the faintest light even of whose fabulous history cannot be traced back to the period when Abraham was driving his flocks over the seats of future empire on the Euphrates. Among Abraham's contemporaries we discern the germ of the great monarchies which first changed the face of human affairs. Nimrod, the founder of Babylon, almost like an Iroquois chief, is chiefly celebrated for his activity and success in the chase. Modern discovery has indeed made us acquainted with tribes existing in a still ruder form; but there is no narrative in which we can trace so distinctly the gradual, yet somewhat rapid, transition made in these favoured regions, from the hunting and pastoral, to the commercial and agricultural states of society.

SECT. I. *The Patriarchal Ages.*

4. *In the early patriarchal records* we discover first the rich Mesopotamian plain, not yet covered with cities and harvests, but standing as an open common, over which the sons of Terah drove unmolested their flocks and herds. In these favourable circumstances, and surrounded by simple and rural plenty, the flocks and the shepherds multiplied in an extraordinary manner. The heads of the families became petty princes, and were as such at once respected and feared. As they went on increasing, the land became "not able to bear them;" and the most intimate friends were able to prevent dissension among their adherents only by an entire though painful separation; nay, even by striking into routes so opposite, as to prevent the possibility of future union. This, however, was rather a palliation than a cure for the evil; for, in whatever quarter each directed his course, he came into contact with other families. The difficulty was still augmented, when all the more fertile tracts began to be cultivated by a

fixed population, subject to regular government. The first regions which came under these circumstances appear to have been Lower Egypt and Gerar, on the coast of Philistia, along the Mediterranean. In the latter we find Isaac attempting to settle and cultivate the ground; but the king, though evidently afraid to offend so potent a tribe, insisted, in a determined though courteous manner, upon their quitting his territory. The family were therefore obliged finally to establish themselves in the vicinity of Hebron, collecting the somewhat scanty herbage which grew amid the rugged mountains to the west of the Dead Sea. It was, therefore, an auspicious change when they were transported into the Land of Goshen, a rich pastoral district of Egypt. The circumstances attending the captivity of Joseph enable us already to observe the activity of that interior caravan-trade, which afterwards, on so great a scale, traversed Arabia. Two caravans, destined for the supply of Egypt, appear meeting each other in opposite directions; and that cruel trade, of which men were the object, is already carried on in the same remorseless manner, and by the same unjust means, by which it has ever since been conducted.

SECT. II. *The Kingdom of Israel.*

5. *The Israelites*, after being established in Egypt for more than two centuries, were led back into the promised land, so long the seat of their ancestors. Every thing there, since the patriarchal age, had assumed quite a different aspect: it presented walled cities, and high cultivation, accompanied with that gross superstition and dissolute voluptuousness which are the too common attendants of early wealth. The guilty inhabitants of Canaan with their country were delivered into the hands of the Israelites; and the territory being divided among the ten tribes, gave occasion to a very careful topographical survey; but nothing yet occurred to attract the views of the nation beyond these limits, or towards the world in general. Still less could this take place during the subsequent period, when they were forsaken of heaven, and reduced to servitude under the neighbouring nations. It was *under the favoured reign of David* that Israel finally triumphed over all her enemies. That great prince left to Solomon, either as subject or tributary, a territory extending from the Euphrates to the Mediterranean and the borders of Egypt, forming the most powerful state then in western Asia. *Solomon*, by the terror of his father's name, and of the powerful army transmitted to him, was enabled to preserve the whole of this kingdom, during a long reign, in peaceful submission. This accomplished prince devoted himself to the arts of peace, to the extension of commerce, to the culture of science, and to the improvement and embellishment of his dominions in every direction. By the alliance with Hiram, he was enabled to accomplish voyages more remote than had, perhaps, been ever undertaken under any former sovereign. His alliance, and even his society, were courted by distant princes; and the observation of the Jews began to extend over a considerable portion of the globe.

6. *The separation of the kingdoms* after the death of Solomon, was a fatal blow to the greatness of the house of Israel. Their divided power could no longer maintain numerous tributaries in submission, nor was it adequate to distant and extensive enterprizes. All the states beyond the Jordan shook off the yoke; the attempts to navigate the Red Sea were abandoned; and all distant regions in a great measure lost sight of. Their view, however, was enlarged by unexpected and unwelcome events from another quarter.

7. *The successive invasions of Assyria and Babylon*, which terminated in the downfall of both the kingdoms, forced upon the Israelites a knowledge of the existence of these proud and powerful empires. At the same time, the colossal grandeur of Egypt, the only power capable of contending with them, was brought into prominent notice. Ample materials were thus afforded for those lofty and awful images, those pictures of the shaking of the world and the downfall of nations, which abound in the writings of the prophets during the regal times. Another and nearer object attracted wonder, and afforded the means of knowledge respecting regions still more distant. This was Tyre, the earliest seat of commerce, in whose markets were found collected the tin of Britain, the gold of Africa, the cottons of India, and, perhaps, the silks of China. This forms so grand a feature, and the descriptions of it tend so much to illustrate early geography, that it must claim some separate notice.

SECT. III. *Commerce of Tyre.*

8. *Tyre*, which under Solomon was already great and flourishing, continued to increase till, with the exception of one of its own colonies, it became the most splendid emporium of the ancient world. It appears, indeed, truly wonderful that, at this early period of arts and history, when Rome yet consisted only of a few straw-built cottages, merchants in Tyre should vie with the pomp of kings. So magnificent was the scene, that the prophet, in announcing the divine intention to destroy Tyre, considers it as implying a purpose "to stain the pride of all glory, and to bring into contempt all the honourable of the earth." (*Isai. xxiii. 9.*) Perhaps, however, commerce in its earlier efforts has a particular tendency to concentrate itself in one point, where alone it finds protection, information, and regular channels; while in the advance of society its streams begin to be more widely diffused.

9. *In the interesting picture of Tyrian commerce* drawn by Ezekiel, the foundation of the

intercourse with Damascus and other contiguous districts, is stated to be "the multitude of the wares of her making;" that is, it consisted in the exchange of her manufactured produce for the raw produce of these rich agricultural districts. There is little specification of the Tyrian manufactures, but the returns were all made in natural products, of the first quality which the soils of Judea and of Syria afforded; from Judea, the finest wheat, honey, oils, and balsam; from Syria, white wool, and the wine of Helbon. No situation could be more fortunate than that of Tyre for the formation of a navy, with the magnificent forests of Lebanon, Senir, and Bashan, rising immediately behind. The timbers, it appears, were constructed of fir; the cedar supplied masts; while the oak was used for those long and powerful oars, which were then the chief instruments of navigation. The vessels appear to have been fitted up with a luxury unknown to modern times. The benches were of the finest cypress wood, inlaid with ivory; the fine linen of Egypt, adorned even with embroidery, was spread out in sails. Tyre, like Carthage, appears to have adopted the policy of employing mercenary troops, which she drew even from the mountainous districts of Persia and the upper Euphrates. The immediate guard of the city, however, was entrusted to its neighbours of Arvad and Gammadim, who, standing round the walls in brilliant armour, are said to have "made its beauty perfect."

10. *With regard to the distant commerce of Tyre*, the quarters to which it was carried on must become the subject of some discussion, in the course of which we shall introduce the interesting particulars given by the prophet.

SECT. IV. *The World according to the Hebrews.*

11. *No System of Geography can be traced in the sacred writers*, who, occupied with higher objects, do not even allude to any such as existing among the Hebrews. The ideas of that people with regard to the structure and boundaries of the earth may, however, be *inferred* from the genealogical chapters (*Gen. x.*, repeated *1 Chron. i.*), which contain, in fact, a view of the known divisions of the earth, agreeing in some striking particulars with the records of profane history; also from the accounts of the commerce of Tyre, and from various detached notices in the historians and prophets.

12. *The Hebrews obviously never attempted to form any scientific theory respecting the structure of the earth.* The natural impression, which represents it as a flat surface, with the heaven as a firmament or curtain spread over it, is found universally prevalent. Beneath was conceived to be a deep pit, the abode of darkness and the shadow of death. In one place we find the grand image of the earth being hung upon nothing; but, elsewhere, the *pillars* of the earth are repeatedly mentioned; and sometimes the pillars of heaven. In short, it is evident, that every writer caught the idea impressed on his senses and imagination by the view of these grand objects, without endeavouring to arrange them into any regular system. Although, however, the Jews never indulged in speculative geography, yet there are copious examples of minute and careful topography for practical purposes. Our object, however, is not to mark the divisions of Judea, but to trace the ideas of the Jews respecting the extent and boundaries of the known world. We shall at the same time be able to collect all that is now to be known of the Phœnician Geography; for it is evident that Ezekiel visited Tyre, as Herodotus did Babylon, with the eye of an intelligent observer; and he would doubtless hold intercourse with the best informed men in that great school of commerce and navigation. The objects always alluded to, as placed at the farthest limits of their knowledge, are Tarshish; Ophir; The Isles; Sheba and Dedan; The River; Gog, Magog, and the north. (*Fig. 1.*)

SUBSECT. 1. *Tarshish.*

13. *Tarshish* is the name which, in the annals of Jewish and Phœnician navigation, occurs most frequently, and ranks next to Tyre; yet nothing has been found more difficult than to fix that name to any precise place. The peculiar difficulty is this; that there are two voyages from Tarshish: one up the Mediterranean, bringing iron, silver, lead, and tin, the produce of Spain and Britain (*Ezek. xxvii. 12.*); the other up the Red Sea, bringing gold, ivory, and apes, the produce of tropical Africa (*1 Kings, x. 22.*). How these two voyages can be from the same place, appears at first sight to baffle research.

14. *Various places* have been suggested, among which I should not think it necessary to mention Tarsus, in Cilicia, were it not supported by such names as Volney and Malte Brun. Except the resemblance of name, it has not a single feature which can be reconciled to the Tarshish of Scripture. Besides, the name *Tarsus* is evidently of Greek origin (*See Steph. Byzant. in v. Strabo l. 14. Bochart's Phaleg., and Wetstein's Nov. Test. vol. ii. p. 511. & 608.*), whereas Tarshish is manifestly of oriental derivation, and is doubtless of Phœnician origin. Indeed, Malte Brun admits it to be tenable only on the clumsy and improbable supposition of there being two places of the name of Tarshish. Tartessus or Cadiz is certainly more plausible, and agrees with the Mediterranean voyage; but the distance is too great, and notice might have been expected to be taken of not a few intermediate objects, particularly of the Straits of Gibraltar. It is altogether foreign to the voyage by the Red Sea. This last objection

Fig. 1. GEOGRAPHICAL SYSTEM OF THE HEBREWS.

appears also to hold against Carthage, which, in every other respect, seems preferable to Tartessus, and of which more will be said in the sequel.

15. To solve the problem of the two voyages, the only attempt, so far as I know, has been in the ingenious hypothesis of Gosselin: Tarshish, according to him, signifies the great or open sea, as distinguished even from the largest of its enclosed gulfs. The name may then be applied equally to the Atlantic and the Indian Ocean; and the voyage to and from Tarshish may equally be by the Red Sea or the Mediterranean. But though this hypothesis be supported by the signification of an old Hebrew term, and though it solve the great problem, I think any one, who attentively traces the various occasions on which Tarshish is mentioned in Scripture, will be satisfied that it has a sense quite different from the loose and vague one here ascribed to it. Let us only read the following verse:—"But Jonah rose up to flee into Tarshish from the presence of the Lord, and went down to Joppa, and he found a ship going to Tarshish; so he paid the fare thereof, and went down into it, to go with them into Tarshish from the presence of the Lord." Do not these words unavoidably suggest a precise port, to which there was a regular packet, with a fixed rate of fare?—not a mere vague setting out into the wide and open sea. If the following expressions can be reconciled to M. Gosselin's hypothesis, it is only by very strained interpretations:—"The kings of Tarshish;—the merchants of Tarshish;—pass ye over to Tarshish;—Tarshish was thy merchant: with silver, &c. they traded in the fairs;—silver in plates is brought from Tarshish, and gold from Ophir;—the daughter of Tarshish," &c. In the genealogical chapters, Tarshish is introduced as one of the sons of Javan. But the other three sons, and every other name mentioned in these chapters, are the fathers of a country and nation; and it would be quite singular if Tarshish alone should have had only *the sea* for his offspring. What a strange idea to call the sea one of the sons of Javan! Indeed, this is so glaringly improbable, that M. Gosselin has recourse to the hypothesis of interpolation—a supposition very unlikely in regard to books held so sacred, and in respect to these chapters among a people so fond of genealogy, and altogether a most unsound principle, as applied to the sacred volume. Finally, I think it very evident, from the general tenour of Hebrew writers, that they had no distinct notion of the Mediterranean as an enclosed sea, and of an ocean beyond it. The expression, "the sea," used in that vague and wide sense, will, I apprehend, be always found to signify the Mediterranean, the Red Sea being designated by that particular term. Thus, there appears to be no motive for adopting M. Gosselin's hypothesis, except the want of any

other by which the problem of the two voyages can possibly be solved. But if another can be stated, which shall solve that problem, and at the same time make Tarshish the very place it might be expected to be, this great question may, perhaps, be considered as settled in a more satisfactory manner than heretofore.

16. *That Tarshish must be, fundamentally, Carthage*, cannot, I think, admit of a moment's doubt. The strongest argument is, that if it be not, then that grand emporium of Mediterranean trade, the colony of Tyre, the place of all others with which Tyre held always the closest intercourse, must never have been named by the prophets, who give such copious and detailed accounts of Tyrian commerce. When Ezekiel was enumerating every place, even the most obscure, with which Tyre held intercourse, can it be supposed that this, the chief of all others, would have been totally omitted? But if Tarshish be Carthage, then that celebrated city holds exactly the prominent place which, according to every circumstance, it ought to have held in relation to Tyre. This general negative argument does appear to me quite irresistible. The details are equally conformable. Carthage in her glory monopolised, almost entirely, the commerce of Spain and Britain. She even took the most violent measures to prevent any maritime power from penetrating to the west of Sicily. There appears no trace of the Tyrians ever proceeding further. They found, apparently, in Carthage, a complete assortment of the commodities of all the countries to the west, and on the ocean — silver, iron, lead, and tin, which were thus naturally viewed by the Jews, and perhaps by the Tyrians themselves, as Carthaginian commodities. With regard to the name, considering that both Tarshish and Carthage are corruptions of the original Phœnician term, they have that rude resemblance which might be expected. The connection is rendered stronger by Carchedon, the Greek name of Carthage, which forms a sort of middle term between them.

17. *The voyage from Tarshish by the Red Sea*, however, which forms the grand difficulty, remains yet unaccounted for; and it can only, I think, be solved in the following manner: I conceive the name of this great African metropolis must have been generally extended to the whole of the continent of Africa. All the names of the continents, we may observe, were originally derived from one of their remarkable and frequented districts. The name of Asia was extended by the Greeks from a tract of that name immediately opposite to their shore, including Troas, Ionia, and some other of the more eastern districts of Asia Minor. Africa they called Libya from the country of that name lying directly opposite to them. With the Romans, Africa derived its name from the very district now in question, called always Africa Propria, being the finest on that coast, and including Carthage. It appears, then, quite natural that a place so very prominent, with which Tyre held such close and constant intercourse, apparently the only place much frequented by her on the coast of Africa, should be associated in her conception with the whole continent in which it was situated. On any other supposition, the Jews and Phœnicians must have had no name for Africa, which is not very probable. It is observable that Tarshish evidently does not comprehend either Egypt or Upper Ethiopia, which countries, in fact, were never by the ancients considered as decidedly African, that continent, according to their conception, having the Nile for its eastern boundary. If we admit Tarshish to be Africa, the whole difficulty respecting the two voyages at once disappears. As the voyage to the northern coast was by the Mediterranean, so that to the eastern coast was of course by the Red Sea. It is in favour of this solution that Jerome, in fact, calls the voyage to Tarshish "an African voyage." The Jews, unacquainted with intermediate countries, had probably a very inadequate conception of the distance between these coasts; at all events, they justly considered them as parts of the same vast expanse of continent.

SUBJECT. 2. *Ophir*.

18. *The name of Ophir*, combined, as it always is, with the most precious of metals, and the most coveted of all commodities, ranks among the distant countries known to the Jews, almost superior in splendour to Tarshish, though not equal in greatness and commercial importance. The voyages of Solomon to Ophir for gold, form the greatest naval enterprise in which the kingdom of Judea was ever engaged. Yet this name has been attended with little less difficulty, and produced scarcely less controversy, than that of Tarshish.

19. *The belief that Ophir was in Arabia* has certainly not a little to urge in its favour. In the genealogical chapters it is always combined with Sheba, or Sabea, which was undoubtedly situated at the south-west angle of Arabia. It was from Sheba that gold (doubtless, the gold of Ophir,) was regularly brought to Judea and Phœnicia. Even Bochart, who thinks himself obliged to seek in India a more distant Ophir, clumsily compounds the matter by making another Ophir in Arabia. He is followed by M. Malte Brun. M. Gosselin, with his usual zeal to restrict ancient knowledge, insists, that there never was any Ophir except the Arabian, and places it in the modern interior district of Dofar. There appear to me, I confess, vast improbabilities in this Arabian Ophir. As an interior district, it must have been nearer, or certainly as near, to Judea as Sheba; and it appears strange, that no direct land communication should ever have been opened with it. Let us consider the mighty oper-

ations of Solomon ; his utmost efforts combined with those of Hiram ; the materials of ship-building conveyed by land over a vast desert ; the most skilful workmen transported to Ezion Geber ; a fleet composed of large vessels, called ships of Tarshish, at last formed, and undertaking a series of voyages, in each of which three years were employed. What a waste of labour and expenditure to obtain a commodity which could have been conveyed across Arabia in two months on the backs of camels ! Yet the repetition of the voyage shows that the article was, in fact, procured on better terms than by the usual channel. In the voyage from Ophir, also, we find new articles never mentioned in relation to Sheba or Arabia, but characteristic of equatorial Africa — ivory, apes, and peacocks. With regard to the close combination in which Sheba and Ophir are always found, it will appear natural enough, when we consider that, unless during the short expedition of Solomon, Sheba appears to have been the channel by which the gold of Ophir was transmitted to Judea and Phœnicia. This circumstance might readily lead the inhabitants of those countries to consider the two as closely connected, though Ophir might be beyond Sheba, and even be separated from it by seas and territories of considerable extent.

20. *The hypothesis which places Ophir in India*, though supported by great names, appears quite untenable. The trade of Ophir bears not the least resemblance to an Indian trade. It does not include the fine manufactures and rich spices which India has always furnished ; and its staple is gold, which never, at any time, was an article of export from that quarter of Asia. India has, on the contrary, always demanded a large balance of specie, and has formed a gulf in which the gold of the west has been absorbed. If we reject India, we shall not certainly, with some *savans*, travel as far as Peru in quest of our object, notwithstanding the slight resemblance of name, and the attempt to eke it out by the expression “gold of Parvaim,” which has some appearance of being synonymous.

21. *The eastern coast of Africa* is the quarter to which all the indications appear very clearly to point. In the voyage to Tarshish by the Red Sea, its name and that of Ophir are always combined ; nay, the voyage, which in the Book of Kings is called the voyage to Tarshish, in the Chronicles is called the voyage to Ophir ; so that it is evident the two are one and the same voyage ; and, if Tarshish was Africa, Ophir must clearly be *in* Africa. There is, however, on this coast no abundant supply of gold till we reach as far south as Sofala ; thus implying an extent of navigation which is certainly somewhat startling. M. Gosselin particularly urges, that in the time of Alexander there was no longer any knowledge of eastern Africa ; and that even the Romans never appear to have penetrated beyond Cape Delgado. On the other hand, it is to be considered that the alliance of Hiram and Solomon united advantages which never existed again in an equal degree. The wealth, naval skill, and ample materials which those great princes could command were scarcely equalled, even by the Ptolemies. After the death of Solomon, the kingdom, split into two, and weakened by continued dissension, abandoned entirely these distant commercial enterprises. A solitary attempt to renew the trade was made by Jehoshaphat, but the vessels prepared for that purpose were wrecked in the very mouth of the port of Ezion Geber ; after which the undertaking was entirely given up. In the calamities which afterwards befel Israel and Judah, and the revolutions which subverted the whole political system of western Asia, it is not wonderful that every trace of this distant intercourse should have been obliterated ; and that the successors of Alexander should have had to enter on a new field of discovery. In support of the supposition of Sofala, there may also be noticed a certain resemblance of name ; and the duration of the voyage, stated at three years, would afford very ample time to reach the Zambese, even under all the imperfections of ancient navigation.

SUBJECT. 3. *The Isles.*

22. *The Isles*, a term which occurs much in Scripture, might be supposed to describe generally those portions of the globe which come under this description ; yet a careful comparison of the different passages in which the word occurs will probably show, that it is used in a much more precise and determinate sense, and is applied to a wide and connected range of territory. The whole of the southern coasts of Europe, consisting either of real islands or of peninsular tracts, appears by the Jews and Phœnicians to have been viewed as a long range of islands. Besides, the terms *νησος* and *insula* were, in periods of remote antiquity, applied loosely to peninsulas as well as islands proper. Among many examples which might be adduced, *one* will suffice — Peloponnesus. The isles, relative to Tyre, appear to have ranked only second to Tarshish as a source of wealth, and in respect of close and intimate intercourse. Tyre is called expressly, “a merchant of many isles :” and the consternation which shook the isles at the sound of her fall ; the dismay of their kings, who are said to have then cast off their robes, and sat on the ground, — all point out the extent and importance of this commerce. *Tarshish, Elisha, Chittim, and Dodanim* are named in the genealogical chapter as the *four* who divided among them the isles of the Gentiles ; but, though Tarshish is so often named in combination with “the isles” among the most distant maritime territories, there is never any indication as if it were itself an island.

The combination is probably produced by the extensive possessions and commerce of the Carthaginians in the western islands and coasts of Europe. These, including the southern point of Italy, were, as already observed, probably considered as insular, and were distinguished by the appellations of the "isles afar off," and "the distant isles of the sea." The "isle" in particular, which Isaiah mentions in such close connection with Tarshish, and which the merchants of Sidon, "by passing over the sea, had replenished," can scarcely be any other than Sicily, an island almost Carthaginian, and containing so many flourishing cities. With regard to the isles of Elisha, they are evidently Hellas, the Greek name of Greece. The only distinctive characteristic, indeed, that of furnishing Tyre with the blue and purple dye, does not recal to us any of the features under which we have been accustomed to recognise that celebrated region. But Greece was not yet the seat of arts and arms; and, had she been so, the Tyrian merchants might still have viewed her only as she served their purpose. Bochart has collected ample testimonies to show that the murex, the shell which yielded those celebrated dyes, was found in peculiar abundance on the coast of Laconia. Chittim appears very evidently Cyprus, and its early capital of Citium. The alarm being given thence of the approach of the king of Babylon, and its being considered as the natural place of refuge for the inhabitants of Tyre, where yet they would not be fully secure, mark a proximity which belongs to no other island. The name, indeed, is in one instance given to Greece, and in another to Italy; but this seems merely to be, that, as the nearest known island, its name is sometimes thus vaguely extended to the whole of that territory considered by the Jews as insular. The attempts of Bochart to find the name of Chittim in Italy have been wholly abortive; for we cannot consider as worthy of notice the observation that it and *Latium*, in the respective Greek and Latin languages, both signify "to hide." In regard to Dodanim, convertible into Rodanim (ד and ר being perpetually interchanged and confounded), though it is mentioned only once, we seem justified in fixing on Rhodes, already flourishing and commercial, though not yet become the rival of kings. Bochart seems to go much too far, when he seeks for it on the Rhone or the Ebro.

SUBJECT. 4. *Sheba and Dedan.*

23. *Of the internal trade of western Asia* during the early ages, the most extensive and important was that carried on across Arabia. It consisted, not so much in the productions of the region itself, as in those of India and Africa, which found their way by this channel to Judea and Phœnicia.

24. *Sheba*, among the Arabian states, holds the most prominent place, being undoubtedly the same with the Sabæa or Arabia Felix of the classic writers. Its imports were the precious commodities of gold and incense: the latter anciently in most extensive demand for the purpose of sacrifice. These articles appear to have been brought to Judea, not by any maritime channel, but in crowded caravans. The "companies of Sheba" are mentioned even in Job. Isaiah speaks of the "multitude of camels;" and of "all they from Sheba." Yet the incense, it is now certain, must have come chiefly from the opposite African coast of Berbera; and the gold, we have seen reason to think, must have been derived from a still more remote part of that continent.

25. *The commerce of Dedan* rivalled that of Sheba, being carried on from the opposite or eastern coast. The mention of "many isles" in combination with Dedan seems to fix it to that point at the entrance of the Persian Gulf, which is, in fact, bordered by numerous islands. One of these, Ormuz, became afterwards the seat of a kingdom, which, from a situation and commerce similar to that of Dedan, derived a splendour which made it the pride of the East. The imports from Dedan — "ivory and precious cloths" — point out the source of this prosperity. These were the commodities of India, brought to the mouth of the Persian Gulf, and thence transported across the desert to the western regions. The caravan trade of Dedan appears to have been most extensive; insomuch that the prophet, in denouncing the judgment upon Arabia, mentions the "travelling companies of Dedanim" as its most conspicuous feature. In the prophets, Edom and Dedan are almost universally named together, and the same judgments represented as affecting both. Hence they are usually considered as parts of the same country, and the ordinary maps include Dedan as a district of Edom. Even Bochart, whose learning showed him that there must be a more distant Dedan, adopts the hackneyed scheme of supposing that there were two Dedans. There is no occasion for so unskilful a theory to explain the intimate connection between these two states. When caravans came across Arabia from the Persian Gulf, it was at Edom or Idumea that they first touched on the civilised world. A depôt was thus naturally formed there of the commodities in which they traded. This traffic raised Idumea and its capital, Petra, to a high pitch of wealth and importance. So close a connection necessarily caused Dedan to be deeply affected by any calamity which desolated Edom, and rendered her no longer the channel through which this commerce could flow. But these disasters are by no means represented as touching her so closely or so deeply; and while Edom is represented as utterly spoiled, and converted into a waste and reproach, the inhabitants of Dedan are merely warned to "turn back and dwell deep" (*Jer.* xlix. 8.); and the expression, "they of Dedan

shall fall by the sword," is more correctly interpreted in the margin, "they shall fall by the sword *unto* Dedan." These circumstances appear to mark, along with an intimate connection, a complete distance and separation between these two great Arabian states.

26. *Raamah* is mentioned among other nations of Arabia, along with Sheba, as producing the same articles, but as a much less remarkable country. It appears to be the modern Hadramauth, neither situated so commodiously as Sheba for the African, nor as Dedan for the Indian, trade. Some of the best-watered districts, probably of the Nedsjed, appear to have composed the kingdom of *Kedar*, enriched by the breeding of numerous sheep and goats, with which it supplied even Tyre, and rose to such prosperity, as to make it be considered a mighty catastrophe "when all the glory of Kedar should fail."

SUBJECT. 5. *Countries on the Euphrates.*

27. *The river* (for such is the import of the term) presents itself as a grand feature of the landscape after passing across the wide Syrian desert, towards the eastern extremity of the known world. This name, in preference even over the Nile and the Jordan, was always applied to the Euphrates, which, holding so immense a course through kingdoms the most celebrated in history, was considered as one of the grand boundaries of the earth. The great empires and capitals of Assyria and Babylon gave to it a lustre, which was scarcely divided by the *Tigris*, whose name was little known to the Jews before the captivity. Along this line of territory Ezekiel enumerates a number of cities, Haran, Canneh, Eden, Ashur, &c., from which great caravans proceeded to Tyre with cloths and other articles of the most valuable description. In such early accounts, however, the country from which commodities last came is seldom distinguished from their original seat. I therefore entirely agree with Dr. Vincent, that they must have been brought by a long overland voyage across Asia; that these chests of rich apparel, so carefully bound with cords, came, probably, by interior caravans from Hindûstan, and, perhaps, already from the frontier of China.

28. *Of the countries beyond the Euphrates*, only some broken fragments of knowledge appear to have reached Judea before the captivity. Elam is particularly noticed; the residence of a warlike people, occupying the long mountainous tract west of the *Tigris*. Media and Persia are also named on a few occasions, but so as to prove that they were only contemplated in dim and obscure distance. At a vague and indefinite distance beyond, the *ends of the earth* were imagined to exist. The early Greeks and, after them, the Arabians, viewed the habitable earth as an island, surrounded on every side by water. Ptolemy, on the contrary, places at every extremity of his map a vague expanse of unknown land. The Hebrews combined in some measure these two views of the subject. To the west, the remotest object for them was the sea, studded with numerous and distant isles; but to the east, where land was seen indefinitely extending, they formed the idea of an inland termination, without being able to attach to it any precise limits. Such a boundary was apparently supposed to exist in various directions, since "all the ends of the earth" is an expression frequently occurring. It was to the east, however, that this idea peculiarly attached itself; and "from the river to the ends of the earth," is the farthest point to which the figurative kingdom of the Messiah is made to extend.

SUBJECT. 6. *Gog, Magog, and the North.*

29. *The north quarter* is the only part of the circuit of the geographical knowledge of the Jews which remains to be surveyed. It presented features of peculiarly rude and formidable aspect. Ezekiel, in anticipating an approaching inroad, draws the most gloomy feature of the hordes which it poured forth: Gog, with all his bands, coming like a storm or a cloud to cover the land; Gomer with all his bands; the house of Togarmah, from the north quarter: "a great company and a mighty army," directing their course against those nations which "were at rest, dwelt safely, and had gotten cattle and goods;" and with the eager purpose "to take a prey, to carry away silver and gold, to take a great spoil." This picture, these hostile and tumultuous crowds, "all riding upon horses," with their wide-roaming and predatory habits, has always suggested the idea of Scythian invasion; and the Arabian geographers have placed the castle of Gog and Magog at the remotest extremity of Tartary. On looking narrowly into the matter, however, we shall find it difficult to suppose this inroad to have proceeded from any part of those unbounded plains. The fact is, we have no occasion to look so far; for the high table lands in the interior and north of Asia Minor, Phrygia, Galatia, Cappadocia, and Paphlagonia, have always presented the same rude pastoral aspect, and have bred tribes of migratory shepherds and warriors, very similar to those of Scythia itself. These tracts, in fact, continue still to pour forth vast bodies of irregular cavalry, which form the main strength of the Turkish armies. This view of the subject appears completely fixed by the account of the commercial intercourse maintained by these nations with Tyre. The prophet mentions Meshech and Tubal, elsewhere completely identified with Gog, who is called their "chief prince." There never has been the least doubt as to the position of these countries in Upper Armenia, and on the southern border of Caucasus. There the classical writers mention the Moschi and the Tibareni, which are, perhaps,

the same names. The imports into Tyre are stated to be "vessels of brass, and persons of men." This somewhat curious combination is, however, altogether characteristic of the region in question, which was, in ancient time, highly distinguished for the copiousness and excellence of its copper and iron, which last is not wholly excluded by the term used in the original. The skill with which it was worked into steel by the Chalybes, a people of this region, caused their name to be generally given to this product. Even in the present state of neglect, the neighbourhood of Trebisonde supplies with excellent copper all the Lesser Asia. The other article, also, is but too descriptive. The expression, "persons of men," marks the trade in slaves, with which it has always been the fate of Caucasian countries to supply the East. Horses and mules are reported as brought by the "house of Togarmah." Horses have always been a boast of Tartary; and an alliance has been imagined between this name and that of the Turcomans, who still furnish the finest horses. But there was a race called Trogmi, in the upland tracts of Paphlagonia, a region celebrated for its horses, and also for its mules, in which last respect it has a decided advantage over Tartary, to which this last breed is a stranger. Thus we seem justified in finding Gog, with all his rude and terrible appendages, in the northern extremity indeed of the civilized and classical world of Asia, but still far distant from those boundless wastes which composed the ancient Scythia and the modern Tartary.

30. *Javan*, which is described as furnishing the same objects of trade with Meshech and Tubal, but not as having any concern in the desolating invasion of Gog, is in fact, the same word with Ion, or Ionia, an extensive appellation, which comprehended all the western part of the Lesser Asia. The Jews and Phœnicians, overlooking the long range of narrow straits which separated it from Europe, not yet recognised as a separate continent, appear to have extended the name to Thrace, and the interior of continental Greece. Alexander the Great is in one place called king of Javan. That a similar extension was recognised in the early ages of Greece itself, appears by the celebrated ancient inscription at the Isthmus of Corinth. "This is Peloponnesus, not *Ionia*." The Javan slaves were probably drawn from Thrace, whose barbarous regions amply supplied the ancient markets with this cruel species of commodity.

CHAP. II.

ANCIENT VOYAGES OF DISCOVERY.

31. *The early voyages of discovery* formed the most important materials for those delineations of the globe which were made by the geographical schools of Greece and Rome in their more advanced and perfected state. Before proceeding, therefore, to consider the systems of these schools, it may be proper to take a survey of the exploratory voyages performed by ancient navigators. These do not appear very considerable in the eyes of a modern mariner. There is not one of them, perhaps, which the captain of a tolerably appointed merchant vessel would not, in the course of his ordinary business, be ready to undertake. But in steering along an unexplored coast, in vessels which could scarcely rank above boats, without the use of the compass, or any correct means of astronomical observation, even these limited voyages were fraught with peril and adventure. The record of them is, however, involved in much mystery and controversy. They were not reported to the world in those regular narratives with which the modern press teems. The ancient narratives are always meagre, and in many cases we have only fragments of hearsay testimony, collected by careless or prejudiced writers. A learned investigation, therefore, is usually necessary, to discover along what coast the navigator sailed, to what point of it he reached, and sometimes whether he ever sailed along any coast. In several cases the most skilful disputants are still divided on questions, which, sunk in the deep abysses of time, must probably remain for ever undecided. Faint and dubious, however, as are these records, they will lead us over some of the most interesting problems of antiquity, and will enable us to trace, in some degree, the infant steps of maritime enterprise.

SECT. I. *Circumnavigation of Africa under Necho.*

32. *To perform the circuit of the coast of Africa* was the favourite object of ancient maritime enterprise, as it continued to be of that of modern times, till the era of its final happy accomplishment. The manner in which its coasts, beyond the Mediterranean and the Red Sea, began to converge, suggested the idea of a peninsula, the circumnavigation of which might be effected, even by the limited resources of ancient navigation. The wide sphere, both of knowledge and trade, which such a discovery would open to the enterprising maritime nations round the Mediterranean, was sufficiently obvious. The first attempt of this description originated in a quarter which had usually been accustomed to keep aloof from every species of naval enterprise.

33. *Egypt* had long held itself as a country strictly agricultural ; but *Necho*, who next to *Sesostris*, raised its military glory to the greatest height, appears, like other conquerors, to have been animated by an active spirit, which exerted itself in every direction. Not possessing fit instruments among his own subjects, he engaged some Phœnician navigators to descend the Red Sea, and endeavour to find their way back to the Mediterranean, by the Pillars of Hercules. The narrative is so very short, that we may easily give it in the words of Herodotus : “ The Phœnicians, setting sail from the Red Sea, made their way into the southern sea ; and when autumn approached, they drew their vessels to land, sowed a crop, and waited till it was grown, when they reaped it, and again put to sea. Having spent two years in this manner, in the third year they reached the Pillars of Hercules, and returned to Egypt, reporting what does not find belief with me, but may, perhaps, with some other person ; for they said that in passing Africa they had the sun on their right hand. In this manner Libya was first known.”

34. *The authenticity of this narrative* has been in a remarkable degree the object of learned curiosity, and has produced a mass of controversy, greater, perhaps, than its short and vague nature is well able to admit. The arguments appear to have been exhausted on the believing side by Rennell, on the sceptical by Gosselin and Vincent. Formidable as the achievement was, it does not seem to involve any absolute impossibility, since the whole voyage might be performed without losing sight of the shore, or launching into the open sea, through which the ancients had no means of guiding their course ; and their smaller vessels, keeping close to the shore, might even possess some advantage over our larger ones, obliged to stand out to sea, and encounter the stormy waves of the Atlantic. Herodotus seems inclined to credit the information, unless, on the ground of one general statement, which, being the very thing that should have happened, and disbelieved only through his ignorance, strongly fortifies our inclination to credit the story.

SECT. II. *The Voyage of Sataspes.*

35. *The Persian monarchs*, after their sway was established over the eastern coasts of the Mediterranean, found the exploration of Africa in some degree their peculiar province. This nation, however, laboured under an aversion and dread of the sea, greater, perhaps, than that of the other orientals. The only effort of theirs on record was one which arose in a singular and rather casual manner.

36. *Sataspes*, a Persian nobleman, having committed a heinous offence, was condemned by Xerxes to a cruel death. His friends, however, persuaded the monarch, that by commuting this sentence into that of a voyage round Africa, he would inflict sufferings scarcely less severe, and might render a national benefit. They prevailed, and Sataspes, having procured in Egypt a vessel and crew, passed the Straits of Gibraltar, and bent his course southwards. He is represented as having beat about for several months, at the end of which he probably reached the coasts of the Sahara. The view of those frightful and desolate shores, and of the tempestuous ocean which dashed against them, might well intimidate a navigator bred in the luxurious indolence of the Persian court. Sataspes was struck with a panic, and measured back his course to the straits. Yet, hoping that time and the degree in which he had accomplished his mission might efface the impression, both of former offence and of present failure, he again presented himself before Xerxes. In giving an account of his voyage, he merely related, that wherever he landed he had seen little men wearing a Phœnician dress, who immediately fled into the mountains ; but his people had done them no injury, beyond carrying off the cattle of which they stood in need. The failure of the ultimate object of the expedition he imputed to the occurrence of an insurmountable obstacle, the nature of which has not been satisfactorily explained. Xerxes, however, accustomed to expect that all nature should be subservient to his will, would listen to no excuse, and ordered the original sentence to be immediately executed.

SECT. III. *Voyage of Hanno.*

37. *The Carthaginians*, as the greatest maritime and commercial people of antiquity, and as decidedly African, might have been expected to make earlier and further progress in the discovery of Africa than any other nation. In general, however, a veil of deep and awful mystery shrouded all the proceedings of that powerful and aspiring people. It is even asserted that they considered as exclusively theirs the whole Mediterranean east of a line drawn across to Sicily, and that they captured all the vessels, and put to death the crews, that were found navigating within these forbidden precincts. The Romans, on the other side, animated by inextinguishable enmity, are said to have industriously destroyed all the records of the literature and history of their fallen rivals. The only fragment that escaped is the *Periplus* of Hanno, which, notwithstanding the scepticism of Dodwell, its editor, the learned world are now generally agreed in considering as ancient and authentic. This celebrated document is so short, that we may find space here for a complete translation of it.

“ It pleased the Carthaginians that Hanno should sail beyond the Pillars of Hercules, and should found cities of the Liby-Phœnicians. He set sail, therefore, with a fleet of sixty vessels, each of which was impelled by fifty oars. They carried with them men and women to the number of thirty thousand, with provisions and

supplies of various kinds. We sailed two days beyond the straits, and founded a city overlooking an ample plain, and which we called Thymaterium. Thence we proceeded westward to Soloeis, a promontory of Libya, thickly shaded with trees, where we founded a temple to Neptune; then turning eastward for half a day's sail, we came into a lake not far from the sea, overgrown with numerous and high reeds, and on whose banks elephants and a number of wild animals were feeding. Having passed this lake in the course of a day's sail, we founded cities on the sea coast, Gaicios, Gytte, Acra, Melissa, and Arambys. Then setting sail, we made our way to the great river Lixus, which flows from Libya. On its banks the Lixitæ, a pastoral race, fed their flocks; with whom we formed ties of friendship, and spent a short interval. The country above them was inhabited by inhospitable Ethiopians, filled with wild beasts, and traversed by very high mountains, whence the Lixus is said to descend; and it was added, that these mountains were inhabited by men dwelling in caves, of a strange appearance, who outran even horses in the chase. Having received interpreters from the Lixitæ, we proceeded along a desert coast till the middle of the second day; when we sailed one day to the eastward, and in the recess of a little bay found a small island, five stadia in circuit. We left inhabitants there, and named it Cerne. This island, on taking an account of our course, we conjectured to be opposite to Carthage; for the navigation from Carthage to the Pillars, and from the Pillars to Cerne, corresponded. Then we came to a lake through which flows a great river called Chretes. That lake contained three islands greater than Cerne; by these, in the course of a day's navigation, we reached the interior shore of the lake, where very great mountains impended over it, inhabited by a rough people dressed in skins of wild beasts, who by throwing stones repelled us, and prevented us from landing. We then sailed into another river, large and broad, full of crocodiles and river horses. We then returned to Cerne; and from thence passed for twelve days along a shore, the whole of which was in the possession of the Ethiopians, who showed a trembling dread of our aspect, and spoke a language unknown to our Lixite interpreters. On the last day, we came to high mountains covered with trees, the wood of which was odoriferous and variously tinted. Passing round these mountains by a navigation of two days, we came to an immense opening of the sea, on the other side of which, joined to the continent, we saw fires of different magnitude glittering at intervals from every spot. Having watered there, we proceeded close along the shore, till we came to an immense bay, which the interpreters called the Western Horn. In it was a large island, and in that island a salt water lake, in which again there was another island. Entering this lake, we saw in the day nothing but forest; but in the night there were many fires burning; and we heard various sounds of musical instruments, and the cries of numberless human beings. Being terrified by these objects, and the prophets also exhorting us to quit the island, we made off, and reached next the fiery region of the Thymiamates, whence torrents of flame poured down into the sea. Here the heat of the earth was such, that the foot could not tread upon it. We therefore took our speedy departure from this place, and after four days' further sail, saw the earth in the night full of flames. There appeared also in the midst of them one lofty fire greater than the rest, which seemed to reach to the very stars; this, when seen by daylight, proved to be a very lofty mountain, called the chariot of the gods. Thence by a navigation of three days, having passed these fiery torrents, we came upon another bay, called the Southern Horn. In its inmost recess was an island similar to that formerly described, which contained in like manner a lake with another island, inhabited by a rude description of people. The females were much more numerous than the males, and had rough skins: our interpreters called them *Gorillæ*. We pursued but could take none of the males; they all escaped to the top of precipices, which they mounted with ease, and threw down stones; but they made such violent struggles, biting and tearing their captors, that we killed them, and stripped off the skins, which we carried to Carthage."

38. *Such is the entire narrative of this most celebrated of the ancient voyages; but it would be impossible to comprise within the same limits even a sketch of the commentaries to which it has given rise among the learned.*

39. *Three leading hypotheses have been formed: one, that of Bougainville, who conceives Hanno to have reached the Gulf of Benin; another, of Major Rennell, who carries his course only to Sherbro Sound, a little beyond Sierra Leone; while M. Gosselin insists upon terminating it about the river of Nun. (Fig. 2.) When we reflect that the first of these courses is upwards of three thousand miles, and the last under seven hundred, an idea may be formed of the excessively vague nature of these data, where all the names are changed, and no one point fixed with such certainty that the others can rest upon it.*

40. *Bougainville contends that his assigned limits do not exceed what may reasonably be supposed to have been passed over by the most skilful navigator of antiquity; in fact, the period of thirty-eight days is precisely the time employed by the squadron sent in 1641 to found the Portuguese fort of Elmina. All the grand features of man and nature described by Hanno are to be found in tropical Africa only; Ethiopians or Negroes; Gorillæ, who are evidently apes or oran-outangs; rivers so large as to contain crocodiles and hippopotami. The great conflagrations of the grass, and the music and dancing prolonged through the night, are phenomena which have been observed only in the negro territories.*

41. *Major Rennell's system retains all the arguments by which that of Bougainville is supported, at the same time that it avoids the extravagant supposition of ancient vessels having made a course of seventy geographical miles in the day. The Gulfs of Bissago and Sherbro present those numerous islands described by Hanno, and not found on any other part of the coast; and even their form seems to correspond to the appellation of Horn, applied by him to these great gulfs. If, then, Hanno's career reached central Africa, there can be little doubt that Major Rennell's hypothesis, or something near it, exhibits his real progress.*

42. *M. Gosselin restricts the voyage within much narrower limits. It was impossible, he urges, that the course could be otherwise than slow in a voyage of discovery upon an unknown sea, where the mariner could sail only by daylight, with constant precautions, and minutely examining every part of the coast. The motions of Hanno were clogged also by the large and incumbered fleet of which he was the escort. Destitute of the compass, and without the power of standing out to sea, he could never, it is alleged, have doubled Cape Bojador, which so long baffled the efforts of the Portuguese. With regard to the features supposed to be exclusively characteristic of tropical Africa, M. Gosselin conceives that Morocco, yet in no degree civilised or subdued, but in the full possession of rude native tribes, would bear a much more similar aspect than now to the interior portions of the continent. The ape tribe and the wild river amphibia might probably fill a region unoccupied by man, though*

Fig. 2. MAP ILLUSTRATING THE VOYAGE OF HANNO.

now, it is supposed, expelled by culture and a more crowded population. The term Ethiopians has been applied, not to negroes only, but to all nations of a dark colour. He conceives, therefore, that Hanno's course could never pass much beyond the frontier of Morocco, and could have reached only a very little further than the estuary of the river of Nun.

43. To decide a point on which such learned men so widely disagree, is what we do not feel very forward to undertake; and really the difficulties appear very great in any view of the subject. The detail of the positions would, on the whole, lead us to prefer the most limited space. Of these positions the island of Cerne forms the key; and the identifying of it with Arguin is essential to the support of the two remote hypotheses. But though it is evident that the whole of the sailing period to Cerne is not given, the time being omitted during which the five cities were founded, yet the general tenour seems pretty inconsistent with so great a way being made along such a difficult and unknown shore. The defect is in some degree supplied by an ancient nautical guide of some authority, called the *Periplus of Scylax*, in which the sail from the straits to Cerne is given at twelve days, a period which Major Rennell admits to be wholly insufficient for reaching Arguin. Ptolemy, indeed, carries Cerne to almost a tropical latitude; but as he keeps it still north of the Canaries, his graduation here is manifestly erroneous, and his authority, on the whole, is in favour of retaining Cerne within the limits of Morocco. The details of Hanno do not appear to be always very satisfactory; but perhaps they might prove more so, did we possess a more accurate survey of this coast than has yet been taken. On the whole, then, the great question is, whether M. Gosselin's solutions can account for the aspect of nature and life being so different from

that of Morocco, and so like that of a negro coast : perhaps here, too, some light might be obtained from a careful observation of the ruder borders of the former empire.

SECT. IV. *Voyages of Eudoxus.*

44. *The ambition of performing the circuit of Africa*, the grand maritime problem of antiquity, was not solely confined to princes and states. Even private adventurers, animated by the ambition of achieving so great an enterprise, and hoping, perhaps, to combine with it opportunities of lucrative commerce, are found in the list of the explorers of Africa. Eudoxus was the most memorable of these adventurers, whose story, however, has come down to us through a very clouded medium. In ancient, still more than in modern times, there existed men whose habit it was to treat with doubt and derision all narratives of discovery that extended beyond the ordinary limits. At the head of this sceptical band stands Strabo, one of the greatest geographers whose works survive, and who forms the chief medium by which these narratives have reached our time ; a most unfortunate circumstance to the fame of these early discoverers. However, in many instances, nature herself has stood forth as their vindicator ; and our more extended knowledge has enabled us to detect the fallacy of the arguments by which Strabo has endeavoured to refute them. This is not particularly the case with regard to Eudoxus ; but really, in Strabo's notices respecting the adventurous life of that bold navigator, we cannot see any thing which tends to controvert the general belief of antiquity, that he had made repeated and spirited attempts to explore the unknown coasts of the African continent.

45. *According to the narratives of Strabo, Eudoxus* was a native of Cyzicus, sent on a mission to Alexandria, then the great seat of maritime enterprise and geographical knowledge. His ardent mind was strongly imbued with the spirit which reigned there ; and he offered himself to Ptolemy Evergetes, the reigning king, as a zealous instrument to be employed in any expedition having these objects in view. There was, at first, some talk of ascending the Nile, and endeavouring to reach its unknown sources ; but their views received a new direction from the arrival of a person who was, or professed to be, a native of India, escaped alone from the wreck of his vessel near the foot of the Arabian Gulf. Ptolemy immediately fitted out a naval armament, with which Eudoxus proceeded on this destination. He appears to have made a prosperous voyage, and to have returned with a cargo of aromatics and precious stones, which last had either been washed down by the rivers, or dug out in a concrete state. It is scarcely probable, however, that Eudoxus ever reached the real shores of India, or went beyond the southern shore of Arabia, and, at farthest, the Persian Gulf. Of this wealth, Evergetes appears to have plundered him ; which Strabo insinuates was in resentment of some dishonest conduct on his own part. We cannot, in these days, attempt to judge between the two parties. However, Evergetes dying, his widow Cleopatra took Eudoxus again into favour, and sent him on a fresh voyage. He was now driven by unfavourable winds to the coast of Ethiopia, where he was well received by the inhabitants, and carried on some advantageous trade. His return to Alexandria was again unfortunate. Cleopatra was dead ; and her son, who succeeded, treated him as ill as Evergetes had done. Eudoxus brought with him, however, one trophy from the extremity of his voyage — the prow of a vessel, said to have come from the westward as the portion of a wreck, and on which was sculptured the figure of a horse. This prow being exhibited by Eudoxus on the harbour, some mariners from Cadiz declared it to be the very form peculiar to a species of large vessel which went from that port for purposes partly of trade, and partly of fishing, to the coast of Mauritania. Eudoxus listened with enthusiastic credulity, and determined now to renounce the deceitful patronage of courts, and to fit out a new expedition from the commercial city of Cadiz. He proceeded thither by way of Massilia and other maritime stations, where he loudly proclaimed his hopes, and invited all who were animated with any spirit of enterprise to accompany him. He accordingly succeeded in equipping an expedition on a considerable, and even magnificent scale. He had one ship and two large boats, on board of which he carried, not only goods and provisions, but artisans, medical men, and even players on musical instruments. A crew so gay, and filled, probably, with extravagant hopes, were ill fitted to encounter the hardships of African discovery. They took fright at the swell of the open sea, through which Eudoxus was anxious to conduct them, and insisted, according to the usual timid system, on being brought near to the shore. This led to the disaster which Eudoxus had foreseen : the ships were stranded, and the cargo with difficulty saved. The most valuable articles were then put on board one vessel of a lighter construction, and he prosecuted the voyage till he came to a race of people who appeared to him to speak the same language with those whom he had met on the opposite shore of the continent. Conceiving himself to have thus ascertained the object of his voyage, he returned, and endeavoured to procure the barbaric aid of Bocchus, king of Mauritania ; but, suspecting that monarch of a treacherous design against him, he again betook himself to Spain. Here he succeeded in equipping a fresh expedition, consisting of one large vessel fitted for the open sea, and another of smaller dimensions for exploring the coast. Here, unfortunately, the narrative breaks off, referring to the Spaniards and Gaditanians, as likely

to know more ; but as nothing more is stated on any authority, we fear that this last expedition must have had an unfortunate issue. Such is the narrative given by Strabo, upon information which seems to have been originally obtained from Eudoxus himself ; and really we see nothing in it unworthy of belief, or which might not very well be accomplished by a man of bold and enthusiastic character, possessed of science and talent, and devoted with such ardent zeal to the cause of discovery. Some of Strabo's own criticisms appear to be very trifling. He asks how it was possible for Eudoxus, after being repeatedly stripped of all his wealth, to fit out always new expeditions on an augmented scale ; but his own narrative expressly states the foreign sources to which he had recourse. Again, it is tauntingly asked, why he turned back in his last voyage, when he found himself so near the attainment of his object ; but surely when he tells us that his whole armament was shipwrecked, and that he had nothing to proceed in but a boat put together out of its remnants, there does not appear the least mystery in his finding it very expedient to return. With as little reason can Eudoxus be made responsible for the fables which antiquity has put into his mouth. He is represented by some as having actually made the circuit of Africa ; by others as having come to one nation that was dumb, and another whose mouth was entirely closed, and which received food through an orifice in the nose. None of these fables are found in the report of Eudoxus himself, as coming through the mouth of Strabo his enemy ; and we may therefore justly conclude them to have arisen out of the propensity to the marvellous operating upon the successive minds of those through whom the narrative passed.

SECT. V. *Voyage of Pytheas.*

46. *The voyage of Pytheas*, the Massilian navigator, is of peculiar interest, as it is the only one described in any detail, having Europe, and particularly the British Isles, for its object. It comes to us, however, still more deeply tinged by the same dim and discoloured medium through which that of Eudoxus has passed. It is known almost solely by the hostile quotations of the sceptical Strabo, adduced for the purpose of proving Pytheas to be "a liar of the first magnitude." Yet, when we find the nature of the grounds on which this conclusion is made to rest, it appears surprising that M. Gosselin, with all his propensity to doubt, should have adopted so eagerly the severe judgment of his predecessor. These grounds, in fact, are such as to place in the clearest light Strabo's own ignorance, and the superior information of Pytheas. This last will become more conspicuous, if we suppose, as seems probable, that the errors of the geographer were transmitted to him from Massilia itself ; in which case, Pytheas being found possessed of knowledge of which his countrymen were destitute, there appears no mode in which he could have obtained it, except the actual performance of the voyages.

47. *The following are statements on which Strabo rests his refutation of Pytheas.* That navigator stated, that the *Calbium Promontorium*, the extremity of Bretagne, pointed to the west, while Strabo affirms it to be perfectly notorious that its direction was to the north. This last strange idea was connected with what we shall find to be the general error of this school, which allowed to France a southern coast only, and not a western one. Again, Pytheas represented Britain as having one of its sides much longer than five hundred miles, whereas, his adversary maintains this to be the dimensions of its longest side, which, according to him, is that opposite to and seen from the shores of Gaul. Finally, Pytheas had reached such a pitch of ignorance and impudence, as to assert that his *Ultima Thule* was farther north than Ireland ; whereas, all well-informed persons, knowing Ireland to be four hundred miles north from Britain, and scarcely habitable on account of the cold, considered it as forming on that side the extreme boundary of the inhabited earth. Thus far it is necessary only to name the charges against Pytheas, to make him shine conspicuous above his enemies.

48. *There are other statements*, it must be confessed, which appear at first sight a little startling. Pytheas describes the longest side of Britain not only as more than five hundred miles in length, but as exceeding two thousand. It is to be observed, however, that while Strabo described Britain as a triangle, having its longest side opposite to Gaul, Pytheas conceived it to have only *two* sides, one of which, consequently reached from the Land's End, or the Lizard Point, to the extremity of Scotland. If we consider this vast extent of coast, with so many winding shores and deep bays, all the sinuosities of which an ancient navigator was obliged to follow, the estimate will appear not very extravagant. Again Pytheas described the coast of Kent as several days' sail from that of Gaul. But the term by which Strabo designates Gaul, is *Κηλτική* (Celtica) ; and it appears from Cæsar, that Celtica formed only one of the three parts into which Gaul was divided, and was bounded on the east by the Seine. Pytheas probably used the term in this restricted and more proper sense ; when the distance assigned became strictly correct. He moreover described the coast of Spain as inhabited by Gallic nations ; it would even seem, that he considered the *Calbium Promontorium* as Spanish. Here he was clearly in the wrong ; but the error will probably be found to have rested not in his observations and facts, but in mixing them with an erroneous theory prevalent at Massilia, according to which, France had not a western coast, nor one

facing the Atlantic ; such a coast belonged to Spain only. Under this impression, Pytheas, so long as he sailed along the western coast of Gaul, and till he came to that opposite to Britain, would naturally imagine that he was sailing along the coast of Spain.

49. *Strabo at last traces Pytheas to Thule*, and "her utmost isles," when he does, certainly, present a narrative assuming somewhat of a fabulous aspect. The most daring navigator, as he approached the dreary boundaries of earth and ocean, and saw only the high billows of the North Sea dashing against a rocky and misty shore, might become liable to some sinister impressions. Pytheas, it seems, said, that beyond Thule there commenced what was neither earth, sea, nor air, but a confused blending of all the three, similar to the substance called *pulmo marinus* (a species of medusa common on our shores). He added, that this substance was the basis of the universe, and that in it, air, earth, and sky hung as it were suspended. This last was evidently a mere theory, though certainly not devoid of extravagance. M. Gosselin, however, has certainly gone much too far, when he says, "It was impossible either to walk, to breathe, or to sail in it ; and yet, if we are to believe Pytheas, in it he walked, sailed, and breathed." Pytheas is evidently represented by Strabo as having merely beheld from a little distance this chaotic compound. "He saw it, and stated the rest from hearsay." Now, as to this asserted view, if we place ourselves in the situation of Pytheas, seeing before him the northern sea, overhung by thick and gloomy mists, shrouded in twilight, and darkened by tempest, we may suppose him very easily persuaded, that what he beheld was a confused blending of all the elements, not very dissimilar even to that thick viscid animal substance to which it was compared. Nor can we feel much wonder, if, after this long and difficult navigation through so many perils, he should lend somewhat of a ready ear to a report which represented him to have reached that farthest boundary of nature, beyond which it was no longer possible for mortal sail to penetrate. Another report of Pytheas was, that at Thule the phenomenon took place which belongs only to the polar circle, — a summer of one long day, and a winter of one long night. Antiquity is somewhat full of rumours of this phenomenon, which science had pointed as likely to take place at a certain latitude ; and there was a general disposition in those who had made any progress northwards to anticipate the term. Considering the loose way in which rumour then spread, it may easily be supposed, that the partisans of this idea might support it by an exaggerated representation of the real statements of Pytheas. One of these (Geminus) merely reports him as saying that the nights appeared to him to last only for two or three hours, a statement which at midsummer would be quite correct. Indeed, we have been assured by persons who have resided in these islands, that at that season there was scarcely any sensible term of darkness. A foreigner, then, visiting the islands, might very readily imagine he had arrived at that point on the globe where the summer was one uninterrupted day.

50. *The theories, which would make Thule any other place than Shetland*, seem not to require much discussion, though there are not wanting learned partisans in favour of each. Iceland would imply too great an extent of open sea for an ancient navigator ; and the period of five days' sail from the continent would be very inadequate. Some Scandinavian writers have claimed Thule as belonging to their own region ; Rudbeck for Sweden ; Saxo Grammaticus, and Schœnning for the Norwegian Tellemach ; Malte Brun for Jutland. These theories seem sufficiently refuted by the single consideration, that Pytheas invariably considered Thule as British, and expressly calls it the "farthest of the Britains." But Jutland or the Baltic he could have only reached by a long navigation along the coasts of Germany, which could never have been performed without the clear perception of having left far behind him every thing belonging to Britain.

SECT. VI. *The Voyage of Nearchus.*

51. *Alexander the Great* was animated beyond, perhaps, any other ancient monarch or sage, with an ardent zeal for discovery. His expedition became almost as much one of exploration as of conquest. Its course was in general by land, and through the interior of the continent ; but his mind was not less deeply fixed upon commerce and maritime discovery. On reaching, therefore, the banks of the Indus, and being obliged by the mutiny of his troops to fix there the termination of his career, he was seized with a desire to explore the lower course of that river, and afterwards the southern coasts of Asia ; a long range completely unknown to the Greeks. The prospects of this voyage, however, were such as to appal the most enterprising of his naval officers. The perils of tempest and shipwreck on this wide and unknown ocean, with those of being driven upon a barbarous and desert coast, appeared almost to preclude the hope of reaching by this long circuit the destined station of the army on the banks of the Euphrates. The inferior officers variously excused themselves from so heavy a task ; and the enterprise appeared ready to fail for lack of instruments, when Nearchus, the admiral of the fleet, came forward and proffered his own services. Alexander unwillingly committed this task to an officer so high in rank, and his intimate friend ; but the earnestness of Nearchus, and the backwardness of all the others, left him at length no alternative.

52. *The voyage down the Indus* was brilliant. Alexander conveyed his army in a crowded

fleet of two thousand vessels. The sound of numberless oars, echoed by the surrounding woods, as they floated down this majestic stream, excited the admiring gaze of the natives. Alexander even accompanied his admiral down the Delta of the Indus, and took a view of the ocean, after which he returned, to lead his army by a most perilous and difficult route through Gedrosia and Karamania to Babylon.

53. Nearchus now began his arduous naval route (*fig. 3.*), after the usual antique preparation of sacrifices

Fig. 3. MAP OF THE VOYAGE OF NEARCHUS.

and games. At the mouth of the river appeared a most formidable obstacle; a rock barring the passage, and against which the waves broke with fury. This was surmounted by cutting a canal across the softest part of the rock, through which the vessels were able to pass at full tide. He then passed the sandy island of Krokali (Corachie), and Mount Eirus (Cape Monze), when, being now in the open ocean, a series of gales began, so heavy and continued, as obliged him to seek the shelter of an excellent harbour formed by an island called Bibacta. The crews here landed, threw up an entrenchment to defend themselves against the natives, and remained for twenty-three days, subsisting chiefly on shell-fish. The wind having abated, they set sail, and came to a coast where water, of which they appear to have needed almost daily supplies, was only to be got by going several miles up into the country. They then passed between a range of rocks, so close to each other, that the oars struck against them on each side. After sailing a considerable space, partly in a narrow channel between a wooded island and the shore, they came to the river Arabius (the modern Pooralee). It gave name to a numerous people, inhabiting all the territory between this river and the Indus. On the other side was the coast of the Oritæ. In proceeding, however, Nearchus met with a dreadful tempest, in which three of his vessels perished, though the crews were saved by swimming, and he with difficulty brought his shattered vessels to the coast. Here he found Leonatus, whom Alexander had detached to open a communication with him, which he obtained only by very hard fighting. Nearchus here spent some time in refitting his shattered vessels, and exchanged those of his crew who had proved themselves less efficient, for fresh men out of the Greek army. Having laid in corn for ten days, they sailed with a prosperous wind, and reached the rapid stream of Tomerus (the modern Wudd). Here the natives, six hundred strong, were drawn up to oppose their landing; a barbarous race, armed with lances six cubits long, pointed not with iron, but with wood hardened in the fire. Nearchus caused a band of his light troops to swim on shore, and to make no movement till they were drawn up in a triple line, then suddenly to raise a general shout, and pour in clouds of darts and missiles. This sudden attack, their shouts, and the glitter of their armour, produced instant and total rout on the part of the natives. They are described as presenting an aspect almost incredibly savage, being covered in a great measure with hair, and having long nails like the claws of wild beasts. Their dress consisted in the skins of animals and of large fishes.

54. The expedition now steering out to sea, and taking a southerly course, observed phenomena belonging to the midsummer of the tropic, the novelty of which struck them with surprise. When the sun was in the meridian no shadow was projected, and when there came to be a little shadow, it declined to the southward. Stars, which were wont to be seen high in the heavens, were now little above the horizon. At Bagaziri (Cape Arrubah) they left the coast of the Oritæ, and entered that of the Ichthyophagi, or fish-eaters, a food which is said to have so remarkably abounded, that even the flesh of the cattle savoured of fish, from their making it, like sea birds, their daily food. The people were hospitable, but could give only fishes and goats. It was not till the Greeks had sailed a considerable distance that at Barna they found some palms, gardens, and verdure. After passing Cophantæ (Guadel), where they obtained a supply of fine water, and Cyiza (Gwutter) on a desert and rocky shore, they came to a small town on a hill a little inland (probably Churbar), where it appeared probable that a supply of grain might be obtained. To possess himself of this, Nearchus had recourse to measures that harmonise much more with the character of a buccaneering freebooter, than with that of an officer of the first prince in the world. The people met him in the most kindly manner, and presented to him roasted fish and other victuals. Meeting their friendly advances, he expressed a wish to visit their city, and being cordially admitted, his first step was to take military occupation of it, and command the natives to lay open to him all their stores of grain. The poor citizens at first flew to arms, but having no means of effectual resistance, were obliged to yield. It proved, however, that they had little except dried fish reduced to powder, and Nearchus could get only a very small stock of grain. In sailing now along an almost desert coast, the stock of provisions became excessively scanty; and they obtained only a poor supply by landing and cutting off the leaves of wild palm-trees. The pressure became so extreme, and was so impatiently borne by the crews, that Nearchus did not think it safe to land at night, lest they should all take flight into the interior. In one place he found a paltry village, all the inhabitants of which fled; but the Greeks found seven camels, which

they killed and eagerly devoured. The same distress continued to press upon them so long as they sailed along the coast of the "fish eaters." Notwithstanding this name, few of them were fishers, or had even boats. They procured this food by immense nets, sometimes a quarter of a mile long, formed out of the fibrous bark of the palm tree. These they placed at high tide across the mouth of little bays, so that when the waters receded, the nets retained all the fish which had been carried up with the tide. The houses of the rich were built with the bones of whales cast ashore, those of the poor with the back bones of smaller fishes. Nearchus descried a number of whales, whose presence was at first made sensible only by the quantity of water thrown up into the air, and tossed as in a whirlpool, a spectacle which struck the sailors with terror, and made the oars drop from their hands. The commander, however, on being informed of the cause, made his crews raise the loudest possible sound by shouts, trumpets, and dashing of oars, which at once kept up their own spirits, and was supposed to induce these monsters of the deep to replunge into their abysses.

55. *The coast of Caramania* was next reached by Nearchus, after passing the fabulous abode of a Persian Circe, who, according to report, was accustomed to seduce the navigator by voluptuous pleasures, and then convert him into a fish. Nearchus now found his distresses nearly at an end, as the soil was tolerably productive in grain and fruits, and there was plenty of good water. After passing Capes Jask and Bombareek, they came in view of a huge promontory stretching far into the sea, called Cape Maceta (Mussendoon), and forming the entrance of the Persian gulf. The great body of the sailors, and even Onesicrotus, an officer high in command, weary of this long navigation, earnestly proposed to land, and march on foot to Babylon. Nearchus justly and strongly insisted that this was in no degree to fulfil the intention of Alexander, whose injunction it was, to survey every coast, every harbour, and every bay, between India and the Euphrates; and that besides they incurred great hazard of being involved in those arid and burning deserts, of which Arabia in a great measure consists. This wise opinion prevailed, and in ascending the Persian gulf they found for the most part a fertile and beautiful coast. In the delightful country at the mouth of the river Anamis (the modern Minab) they landed, and began to refresh themselves after so many hardships. Nay, a party having proceeded to some distance into the interior, met, with tears of surprise and joy, a man in a Greek dress, and speaking the Greek language. This proved to be a soldier who had straggled from the army of Alexander, which he reported to be at a distance of only five days' journey. On receiving this intelligence, Nearchus caused the ships to be drawn on shore, a rampart to be formed round them, and the crews to take rest and refreshment, while he and Archias set out alone for the camp. On their arrival, they presented an aspect so haggard, pale, and squalid, that the persons they met did not know them, but on being told their name, hastened to carry the first tidings to Alexander. They added (a hasty conclusion formed from appearances), that the fleet and the army had perished. Alexander received Nearchus with a kindness mingled with sorrow, and after the first salutations, began to ask particulars of the catastrophe of his favourite armament; but when Nearchus replied, "O king! thy ships and men are safe," the conqueror burst into a flood of tears, and swore by Jupiter Ammon, that he derived more pleasure from this event than from the entire conquest of Asia.

56. *The rest of the navigation of Nearchus*, when he had with some difficulty regained the fleet, was easy, care being taken that he should find on the coast every kind of supply. They passed the barren and desert rock of Organa, afterwards so celebrated under the name of Ormuz, the large and fertile Oaracta (the modern Kishme). Soon after they quitted the coast of Caramania and entered that of Persia proper (the modern Fars), which they followed till its termination at the river Arosis (the modern Endian Tab), which appeared to them the largest they had seen since they had left the Indus. They were now in Susiana, and soon reached the mouth of the Tigris, where the voyage terminated.

57. *The circumnavigation of Arabia*, and the opening of a communication between the Red Sea and the Persian Gulf, formed to Alexander an object of almost equal ambition. He accordingly appears to have sent expeditions down both seas, in the hope of accomplishing this object. Those, however, who went from Persia were never able to double that formidable promontory (the Mussendoon) which Nearchus had passed at the entrance of the gulf; while those who went from Egypt, after making a certain progress, were always obliged to return for want of water. The narrator chooses to conclude with inferring, that such an achievement must be beyond human skill or power, otherwise the daring curiosity of Alexander would certainly have accomplished it. He reinforces this argument by observing, that as caravans which crossed Arabia were able to travel only during the night, and in the day were unable to bear the intense heat of the sun, it was unreasonable to suppose that region still farther to the south should be at all habitable.

SECT. VII. *Periplus of the Erythrean Sea.*

58. *The complete establishment of the dominion of Rome* produced a long period of comparative peace. The encouragement of industry and commerce never formed part of the policy of that powerful empire; but the demand for luxuries of every description in its overgrown capital, where the wealth of the world was collected, and to procure which the remotest extremities of the earth and sea were ransacked, powerfully stimulated mercantile enterprise. Alexandria continued still the great nautical school, by whose mariners the obstacles which in the time of Alexander had been deemed insurmountable were completely overcome. Regular voyages were established across to India, and for a considerable extent along the eastern coast of Africa. The course of this commercial voyage is related by Arrian, not the historian of Alexander, but a merchant of Alexandria; and though not so much a voyage of discovery as a coasting guide, it is founded, probably, upon personal observation, and will enable us to complete the survey of the great naval routes of the ancient world.

59. *The voyage down the west coast of the Red Sea* began with Berenice, founded by the Ptolemies, and the site of which, after being long sought for in vain, seems to have been nearly fixed by Belzoni. The coast on the African side was wild, and occupied only by a few rude huts of barbarous Nubians. The small port called Ptolemais Theron was the only place where refreshments could be obtained. At length, the navigator came to Aduli, a great emporium, whose site Mr. Salt seems to have ascertained in the vicinity of Arkecko. Here was a profusion of excellent ivory, collected and sent down from Axum, the metropolis, about eight days' journey in the interior. In return for this single staple of Ethiopia was exchanged that variety of commodities which is usually communicated by civilised to barbarous nations; coarse cloths, with bright showy colours, suited to a rude taste; pottery and glass vessels, the manufacture of Diospolis; brass for vessels and ornaments, iron for pointing lances, arms, and cutting instruments. Some fine cloths, and ornaments of gold and silver, were brought as presents or tribute to the king. Farther down, apparently in the Gulf of Zeyla, was the kingdom of Zoskales, a prince who is described in glowing terms as adorned with every virtue, and eminently skilled in Grecian literature; but these seeds of civilization, if they ever existed, did not ripen in so ungenial a climate. The coast now turns westward to the Indian Ocean.

60. *A view of the passage down the opposite or eastern coast of the Red Sea must now be taken.* Navigators do not seem to have ventured across the breadth of that sea from Berenice, but went by Myos Hormus, along the mouth of the Gulf of Suez, touching at *Leuke Kome*, the fair village, which formed the port of the great commercial capital of Petra. The coast downwards was most unfavourable to navigation, "full of danger, without harbours, beset with rocks, every where full of horror;" and such the whole of the Red Sea is described to be by modern navigators. If a vessel was driven too near the shore, it was immediately plundered by the barbarous inhabitants, and all who survived carried into slavery. At length they came to the Burnt Island, which seems to be Gebel Tor, on the coast of Yemen, where they found a fine country and a friendly people. The emporium of this coast was Moosa, near the modern Mocha, said to be inhabited by a race skilled in maritime affairs. The imports were of the same description as at Adulis, but of finer quality, including a considerable quantity of dye-stuffs. The exports were myrrh, gum, alabaster (no mention yet of coffee). They then proceeded downwards, and passed the straits now called Bab el Mandel.

61. *The southern coast of Arabia* formed the next object of navigation. Ocelis (the modern Ghella) was a good harbour, though with little trade; but Arabia Felix, which seems to have been near the site of Aden, had been a most flourishing port, forming a depot in which the merchants of Alexandria found all the commodities of India. It had lately, however, been destroyed by the Romans. In coasting along Arabia, they found Kane (the modern Macculla); the Gulf of Sachalites, in which is found the modern Sahar; and Syagros, described as the largest promontory in the world, usually supposed to be Ras el Had, but which Vincent appears clearly to fix in the much more westerly position of Cape Fartash. This region is described as yielding a considerable quantity of incense, but as extremely moist and unhealthy. They now passed Mosca (Morebat), Asichone (Hasec), the islands of Zenobius (Curia Muria), and came to Ras el Had, where the coast turns northward to the Persian Gulf. The writer observes, and truly, that the entrance of the gulf is bordered by very lofty and rugged mountains; he mentions the celebrated pearl fishery on its western shore, and Apologos, otherwise called Oboleh, then the emporium of the Euphrates. He does not dwell, however, on these details, and passes also, with very slight notice, the southern coast of Persia, which the observations of Nearchus had shown to be destitute of any materials for commerce.

62. *The coast of India* (fig. 4.) now commences, and forms the most important era in the voyage. He reaches the mouth of the great river *Sinthus*, by which name he designates the Indus. It is represented as entering the sea by seven mouths, only one of which is navigable, and on which is situated a place called Emporium Barbaricum, subject to the interior metropolis of Minnagara, which last is described as a Scythian city. The idea of Scythia attached to this part of India could only be suggested by the rude pastoral manners of the people, and combined with the circumstance of its being included in the Parthian empire, points out Minnagara as belonging to what is now called the kingdom of Caubul, to which, in fact, the Delta of the Indus is still subject. The merchants were obliged to go up to Minnagara, and to negotiate with the prince himself. After passing the Indus, navigators found successively the gulfs of Eirin (Cutch) and of Barygaza (Baroach). The narrator here remarks the dangers of every kind with which these gulfs are beset, shallows, concealed rocks, narrow and difficult entrances, but, above all, the extraordinary occasional violence of the tide; in consequence of which, unexperienced navigators often saw their vessels either sunk or driven on shore. Frequently, when they were sailing in perfectly smooth water, a sound was heard as of an advancing army; and soon the tide rushed on with such force, that no anchor could secure the vessels. Barygaza was a very great emporium, at which were found the same commodities as at Emporium Barbaricum, with much finer cloths, and a quantity of long pepper. Ozene (Ougein) was a great interior capital, the prince of which it was necessary to propitiate, by sending up handsome presents of the very best wine, rich unguents, cloth, and beautiful female slaves.

63. *The region of Dachinabades* (the Decan i. e. the South, for Arrian remarks, *Δάχαινος καλεῖται ὁ νότος τῇ αὐτῶν γλώσσῃ*) extended to the south of Barygaza, and is described as combining "many regions, deserts, huge mountains, wild beasts of every kind, and finally, many great and populous nations." It had two large interior capitals, Plithana and Tagara; the one twenty days' journey south from Barygaza, the other ten days farther. The grandeur of both has sunk under the changes to which eastern cities are subject; but the site of the former seems recognised in Piltanah on the Godavery, that of the latter in Deoghir, now Dowlatabad, in whose vicinity are the magnificent sculptured temples of Ellora. A number of ports are now described, which cannot be very precisely determined; but Kalliena, mentioned as the seat, though with some interruptions, of a very great commerce, is pretty clearly recognised at or near the modern Bombay. Afterwards we may know the Concan by the mention of pirates. At length the Greeks reached Limyrike, a fine port, and the seat of a great trade. The three chief emporia were Tyndis (Barcelore), Muziris (Mangalore), and Nelkunda (Nelisuram). This last, which has sunk into a place of very secondary importance, was then the chief southern, as Barygaza was the chief northern, emporium of western India. The larger Greek vessels had even, by availing themselves of the monsoon, been enabled, with a daring course very foreign to the usual habits of ancient navigation, to steer directly across from the mouth of the Red Sea to Nelkunda. The grand staple then, as now, was pepper; to which were added pearls, and precious stones of various descriptions, among which were diamonds and hyacinths, cotton cloths, tortoise-shell, and betel leaf, from the interior. Among the imports, according to the usual course of Indian trade, stood foremost "much money," a little cloth, and a little wine; but a considerable quantity of metals and toys, brass, lead, tin, glass, coral, stibium for painting the eyes, orpiment, and cinnabar. There is much appearance that Nelkunda was the farthest point to which Greek navigators actually penetrated, and that they found there a supply of the commodities produced in the more eastern regions.

Fig. 4. PERIPLUS—COAST OF INDIA.

64. *All beyond Nelkunda* is faint and tinctured with fable. We recognise, however, Comar (Cape Comorin), Taprobane (Ceylon), and its great pearl-fishery. The Coromandel coast is nearly a blank, till we arrive at Masalin, which, with the great abundance of its cotton cloths, speaks clearly Masuhpatan. In proceeding northwards, navigators came to strange and barbarous people, with visages sometimes of enormous length, at others resembling those of horses, and some eating human flesh: an exaggerated picture of the fierce predatory races who occupy the mountain and jungle tracts of Orissa. He describes accurately, however, the direction to the east which the coast of the ocean takes, before it receives the mighty flood of the Ganges. At its mouth there was then, it seems, a great emporium bearing the name, which no city now does, of the river itself. The staple was "superlatively fine cotton cloths, called Gangetic," and which still exist in the superb fabrics of Dacca and Moorshedabad.

65. *In the regions beyond Ganges* the author of the *Periplus* gropes almost in total darkness. Mention is made of an island, the farthest part of the world to the east, and which is richly stored with the most precious productions of the countries that lie on the shore of the Red Sea. This cannot seemingly be any other than Sumatra, though erroneously placed near the Ganges. The only ulterior position is Thinae, a great interior city, situated opposite to Pontus and the Caspian Sea, and near to where the Palus Mæotis flows into the ocean. This strange site we shall afterwards find reason to consider as a combination of some actual rumours with the theory formed by the first Alexandrian school respecting the form and dimensions of the continent of Asia. There seems some reason, however, to conclude with Dr. Vincent, that this Thinae, whence caravans came by way of Bactria to Barygaza, must have obscurely indicated the capital of China. Nor can we be easily persuaded that in the *malabathrum*, though most usually applied to betel leaf, some confused idea of *tea* is not involved. Its being so strictly characteristic of China, and being brought by persons of a broad forehead, short body, and flat nose, features decidedly Mongol and Chinese, seem all in favour of this supposition, and inconsistent with that, which would make it merely betel leaf, a product of Indostan; though there is doubtless a great and manifest confusion between the two substances.

66. *We must now look back to the Straits of Bab-el-Mandel*, and follow our author along the African coast. (Fig. 5.) From those straits vessels proceeded eastward along the shore opposite to Arabia, the modern Berbera. Its ports, Avalites, Mosylum, Mundos, Daphnon, and others, cannot be easily identified on a coast, with respect to which we have scarcely any modern data. The imports were nearly the same as at Adulis; the exports were myrrh, frankincense, a species of cinnamon called casia, some other aromatics, slaves, and a little ivory. At length they doubled the promontory of Aromata (Guardafui), when they came to a coast stretching to the southward and facing the Indian Ocean. Here was a port, the seat of a considerable trade, but by no means secure; however, when the north wind began to blow with dangerous violence, the vessels found shelter in the neighbouring promontory and port of Tabai. Proceeding onwards, they found Opone, Apokapa the less and greater, Nicon, Serapion, seven successive rivers, with anchorages at the mouth of each. Soon after, at the distance of about three hundred stadia from the continent, there occurred a low wooded island, bearing the very expanded name of Eitenediom-menouthesias, which other writers wisely contract into Menuthias. It contained no wild animals, but abounded in fish, particularly tortoises, which the inhabitants were very diligent in catching. Two days' voyage farther brought them to Rhapta, a promontory and port, and the seat of a great trade. Beyond this point, the ocean was not yet explored; but it turned to the west and south, and was supposed to continue in that direction till it joined the Atlantic. The exports from this coast were ivory in great abundance, but not equal in quality to that of Adulis; tortoise-shell, superior to every other except that of India; and a number of valuable slaves, chiefly destined for the Egyptian market. The territory was governed by a number of petty kings, all owning the supremacy of Mopharites, who was himself tributary to Moosa, by the vessels of which great commercial state the trade of this coast was almost entirely carried on.

Fig. 5. PERIPLUS—AFRICAN COAST.

67. *The extent of coast thus described by the author of the Periplus* has been the subject of considerable controversy. Dr. Vincent fixes Rhapta, its farthest point, at Quiloa, thus allowing a navigation of upwards of fifteen hundred miles; while the rigid scepticism of M. Gosselin, placing it at Brava near the mouth of the Doara, allows a good deal less than half that distance. Dr. Vincent here, however, appears to carry the question triumphantly, by means of his seven mouths of rivers, of which M. Gosselin admits that no trace can be found within his limits. They are clearly presented by the estuaries of the Quillimanci, on which are the important harbours of Patte, Melinda, and Mombaza. But we cannot, with Dr. Vincent, pass by Pemba and Zanzibar, to find in the little island of Monfia the Menuthias of Arrian. Zanzibar, from its size and its proximity to the coast, appears a feature which it was impossible to overlook, and its position is in much better bearing with the seven estuaries previously passed. The next cape must then be Rhapta, and this will be that opposite to which

is situated the small group of the Hinagie Islands. Beyond it for a considerable distance the coast runs in the direction of south-west, which does not at all admit the placing Rhapta beyond Quiloa, nor, indeed, on any other part of the coast till after we pass Mosambique.

CHAP. III.

GREEK GEOGRAPHY BEFORE ALEXANDER.

68. *Greece is regarded by all civilised nations as their instructress in the sciences, many of the most brilliant of which she carried to the utmost perfection. In that of geography, however, little progress was made until the formation of the Greek kingdom in Egypt under the Ptolemies. Neither extensive commerce nor distant conquest characterised the Grecian states, otherwise so illustrious for all the arts of peace and war. It was not till the conquering career of Alexander, that the survey of the Greeks was extended over the wide circuit of the ancient world. Engaged before that era in the glorious defensive war against Persia, and the contests with each other for pre-eminence, they confined their views very much within the limits of Greece and its neighbouring coasts and islands.*

69. *The first traces of Greek geography are found among its poets, whose brilliant fancy has spread its lustre over all the regions with which Greece ever held intercourse. Homer took the lead, and his high authority gave to the geography of the Greeks a poetical cast, which they transmitted to the nations whom they taught, and of which the traces are not entirely obliterated.*

SECT. I. *Geography of Homer.*

70. *It is in Homer that we find the first trace of the widely-prevalent idea, that the earth is a flat circle, begirt on every side by the ocean. This was indeed a natural idea in a region so entirely insular and peninsular, nowhere presenting, like Judea, a vast tract stretching so far as to give the idea of immeasurable distance. The circular shape was suggested by that of the visible horizon; and until science demonstrated the globular form of our planet, the very natural opinion prevailed that the earth was a flat circle, with the vault of heaven above, darkness, and the abode of departed souls beneath.*

71. *Homer, like Hesiod and the ancient poets generally, delights in topographical detail, and scarcely allows a city or natural object to pass without applying to it some characteristic epithet. It was only, however, within a very limited range that he could give these distinct and animated notices. The Greek islands, beautiful and fertile spots, which seem to have been the first cradle of European civilisation, were the central point from which his knowledge emanated. He knew well, and had probably visited, on one side Peloponnesus, Attica, and the regions immediately adjoining; on the other, the western coast of Asia Minor, and the banks of the beautiful rivers by which it is watered. Perhaps scarcely any other tract on the globe presents within the same compass such a variety of grand and beautiful objects to rouse the imagination. Beyond this circuit the world of Homer was soon involved in mysterious obscurity. Some grand and distant features, discernible through the gloom, were exaggerated and distorted by ignorance and superstition. Thebes, the mighty capital of Egypt, when that kingdom was in its greatest glory, is celebrated for its hundred gates, and the hosts of warriors which they sent forth to battle. Beyond lay the Ethiopians, deemed the remotest of men, dwelling on the farthest verge of the earth, and to whose distant confines Jupiter repaired to hold an annual festival. In the western part of the same continent the stupendous ridges of Atlas had excited in Grecian fancy the image of a gigantic deified being, to whom was intrusted the support of the heavens. Even farther to the west, the exploits and wanderings of the great Grecian demigod had conveyed a tradition of the strait leading into the ocean, and of the rocks on each side, celebrated under the denomination of the pillars of Hercules. On the east, Colchos was distinguished by its early wealth and commerce; it was considered a city on the ocean, with which, therefore, the Black Sea must have been confounded; and being supposed to contain the palace of the Sun, where during the night he gave rest to his coursers, and whence in the morning he drove his chariot to its diurnal career, Colchos must have been regarded by Homer as placed on the most eastern verge of the earth. On the north, Rhodope, under the name of the Riphean Mountains, was considered a chain of indefinite extent, closing in the northern limits of the world. The poet, however, had heard a vague report of the Scythians, under the description of a people subsisting on mares' milk. The vessels which conveyed the Grecian army to Troy were evidently little better than large boats; and all distant voyages, or those in which land was lost sight of, were considered as fraught with the extremest peril. A navigation to Africa or to Sicily took place only through tempest, terminating usually in shipwreck; and a return from these shores was esteemed almost miraculous. In regard to*

Sicily, indeed, Homer has largely communicated his ideas, having made it the theatre of the woes and wanderings of the hero of the Odyssey. Making every allowance for poetical licence, we see evident traces of the terrified and excited state of mind in the navigators who returned from these shores. Monsters of strange form and magnitude, who watched for the destruction of the mariner, and even fed upon his quivering limbs; delusive sirens, who lured but to destroy; imprisonment under the transformed shape of wild beasts; these, probably, are only a highly-coloured repetition of the terrific rumours brought by the few whose bark had been wafted to those as yet savage coasts.

SECT. II. *Poetical Geography.*

72. *An ideal and poetical character* was communicated to the science of geography itself by the fables with which Homer thus tinged his narrative. This tendency indeed did not rest solely upon Homeric influence, but proceeded from certain secret workings of the human heart. There exist in man ideas and wishes for which, in the sphere of his actual existence, he can find no corresponding objects; these he creates for himself in that dim boundary which separates the known from the unknown world. There involuntarily arises in his breast a longing after a more exalted state of existence than the world before him presents — bright scenes, which he seeks but never finds in the circuit of realities. In a newly-discovered region, however, which possesses any share of beauty, imagination soon heightens the colours of nature, till they appear to fulfil its fond anticipations. Such were those brilliant spots celebrated by the poets under the title of the Gardens of the Hesperides — the Fortunate Islands — the Isles of the Blest — for which, when knowledge had dispelled the first illusion, and brought them down to the ordinary level, a place was still found in some more distant extremity of the globe. Northern Africa, as it stretched westward, was peculiarly adapted, by its striking and brilliant contrasts, to excite these illusions. The first site of the Hesperian gardens was at the frontier of Cyrene, where they are described by Scylax as forming a luxuriant grove, in which the lotus and the palm were mingled with the finest trees of Europe. Other and more western sites were successively found, both for them and the Fortunate Islands, which last were finally fixed, probably on very imperfect observation, at the Canaries. These islands have not altogether lost the appellation; and they are painted by Horace in glowing colours as a refuge still left for mortals from that troubled and imperfect existence which they experience in every other quarter of the globe. Independent, however, of this bright and romantic enjoyment, there are other objects of fond desire to the human heart. In this agitated world it sighs after peace — a scene of profound repose, exempt from the tumults of passion and the corrosion of care. Such a scene, indeed, would never fulfil the hopes thus formed; yet these hopes spring from a natural illusion, to flatter which Grecian poetry conjured up a fabled race, the Hyperboreans, seated in the recesses of the North, and sheltered by vast mountains from the rage of the elements. They were represented as exempted from all ills, physical and moral, the change of seasons, sickness, and even from death. The original seat assigned to them was behind the Riphæan Mountains, which seem to have been originally Rhodope, the northern boundary of the Homeric world. The Greeks having soon acquired knowledge sufficient to ascertain that no such people was there to be found, sought them next on the banks of the Danube; but every thing there was remote from that tranquil aspect under which the poets had painted the Hyperborean world. Some traditions carry them westward; but their seat was finally fixed in that northern extremity of Asiatic Russia which the ancients never explored. They even carried with them the Riphæan Mountains, which became thus an ideal chain, delineated in modern maps as extending along the extreme frontier of Europe. Impressions of gloomy darkness, and even of the termination of existence, are, in other moods of the human mind, associated with images of distance and obscurity. These influences gave birth to the Cimmerians, a people who dwelt in perpetual darkness, and were never illumined by the cheerful rays of the sun. Their favourite seat was on the straits at the mouth of the peninsula of Taurida, the farthest point, probably, of which rumour had spoken in the poetical ages, and which was called the Cimmerian Bosphorus. It was probably from similitude of name that they were afterwards confounded with the people called Cimbri. The learned, however, have found traces of Cimmerians in the extremities both of the east and the west; and the idea of the earth as terminated by a boundary of darkness, being founded on natural impressions, has very generally prevailed. Park mentions it as the reigning belief among the Mandingos at this day; and the world, in the system of the Arabian geographers, was enclosed by a sea of darkness.

73. *Other fabulous creations*, springing from those of Homer, continued long to hold a place in geography. The one-eyed Cyclops appears under the name of Arimaspiæ on the frontier of India, and in the remotest extremity of Africa. The Pigmyes multiplied still more extensively; they had seats on the Strymon, the Hebrus, in India, and the north of Europe. According to Strabo they were spread over the whole southern border of the earth; and this representation even induced Banier to suspect that, on that side, they have been confounded with the monkeys.

SECT. III. *School of Miletus.*

74. *The astronomical schools of Miletus and Samos* appear, so far at least as there is any precise record, to have made the first attempts to form geography into a system, and to apply to it the lights derived from astronomy. These and other cities of Asia Minor rank high among the early seats of commerce, and they established colonies in various quarters of the Mediterranean and the Euxine. While they continued independent they were very wealthy and prosperous, and the sciences were cultivated with ardour and success. To a commercial people practical mathematics, and especially those branches subservient to geography and navigation, must have peculiarly recommended themselves. Thales, Anaximander, Anaximenes, and Pythagoras, are celebrated by their countrymen as the inventors of all the processes by which the phenomena of the globe are calculated. The gnomon or sundial, for ascertaining the progress of the sun from tropic to tropic, and finally the latitude of particular places, the division of the year into 365 days, and into four seasons, are represented as having originated in this school. It appears doubtful, however, whether these discoveries were due to their own exertions or borrowed from the Egyptians and Chaldeans, whose fame, amid the dim traditions of antiquity, stands pre-eminent for astronomical observation.

75. *The first rude mode of forming a division of the earth was into climates*, determined by the species of animals and plants produced in each. Thus the negro, the rhinoceros, the elephant, were considered as characteristic of the torrid zone. This very loose method gave place to another, formed by observing at each place the length of the longest and shortest days. This could only be done with accuracy by a gnomon or dial, erected on a horizontal plane, and showing, by the length or shortness of its shadow, the elevation of the sun above the horizon. There is much reason to think that this simple instrument was employed by the Egyptians, especially in the operation, which they undoubtedly performed, of adding five days and a quarter to 360, the number originally supposed to form a complete year. It has even been imagined by some, that the pyramids, those enormous structures by which this people excited the astonishment of the world, were only huge sundials; and though it might doubtless be extravagant to conclude this to have been their sole object, yet it really appears that, being placed in the direct position of the cardinal points, they are perfectly fitted for being thus employed. But, though it is clear that Thales and his disciples had largely drawn from these early sources, they probably made considerable additions to the information thence derived. Two books, one on the tropic, and the other on the equinoxes, are reported to have been written by Thales himself. The degree of knowledge thus attained enabled him to discover the error of the vulgar in supposing the earth to be a plane surface; but he could not reach the precise idea of its globular form. Anaximander viewed it as a cylinder; some compared its form to that of a boat; others to that of a lofty mountain. The details of the Pythagorean cosmography have not reached us; but the fact that they placed the sun in the centre of the system, with the earth moving round it, indicates at that infant era attainments which were lost during many ages, and only recovered at a far more advanced stage of modern science.

76. *The map* must, as soon as geography was cultivated, have occurred as the best and most perspicuous form of embodying its results. Anaximander is the first who is reported to have constructed a map of the world, embracing that limited sphere of objects which were then comprehended under that term. But the most celebrated production of this nature was that employed by Aristagoras, the prince of Miletus, to induce Cleomenes, the Spartan king, to undertake the conquest of Persia. He entered, it is said, the presence of that monarch, holding in his hand a tablet of brass, on which were inscribed "the whole circuit of the earth, the sea, and all the rivers." Under this pompous description, however, was probably included little more than a route from the Ionian sea to Susa, which was specially pointed to as that by which the Spartan prince might lead his victorious troops to the Persian capital. Even of this line, respecting which he was so deeply interested, the short detail of Herodotus shows him to possess by no means complete information. Beyond Cilicia his descriptions are very indistinct. He has omitted Media altogether, and has given to Armenia quite an undue extension.

77. *The continental Greeks*, during the era of their greatest power, did not cultivate systematic geography, nor indeed any sciences dependent upon mathematical principles, with much activity; indeed, they did not even keep them up to the state in which they had been received from the Ionian cities. One solitary observation of latitude is recorded as having been made at Athens, by Meton and Eudemus, 432 years A. C. The different states, in the course of their extensive wars, must have acquired a great portion of that topographical knowledge which is indispensable for military operations. Engrossed by these internal objects, their attention was little directed to the general system of the world. One individual alone, by extensive travels and diligent enquiries, procured an ample accession to the science of history and of historical geography.

SECT. IV. *Geography of Herodotus.*

78. *The system of geography included in the great historical work of Herodotus* is as complete as could be formed from the materials within his reach. It comprises a general summary of all that he could learn respecting the human race, and the regions which they inhabited. His information was obtained not solely or chiefly from books, but mostly by travelling, the only mode in which at that era geographical knowledge could be effectually collected. He assures us that he had visited Persia, Assyria, Egypt, Thrace, Scythia, and all the distant regions which he describes. He viewed them, however, only as tracts of territory, the abode of men, and did not attempt to combine them into any system of the earth; nor did he possess, or, at least, apply any of the mathematical or astronomical principles of the Milesian school. He even derides some of its conclusions; as that of the earth being round and encompassed by the ocean. His strange statement, that the sun in India was vertical in the morning instead of at midday, is evidently a misunderstood report of what he had been informed respecting the difference of time in the different parts of the earth's circumference. His knowledge, however, such as it is, consisting of plain facts, untinged with theory, is both solid and extensive.

79. *The division of the earth into three quarters, or continents*, was by this time completely formed. Sea, or at least water, seems to have been the principle of separation, though not

required to be altogether complete. Setting out from Europe, for the origin of which appellation we have nothing but the fable of Europa, the Greeks seem to have named the other continents from the districts immediately beyond the intervening sea. Homer already mentions the name of Asia as applied to a large and fine tract on the coast of Ionia. Thence it spread through the spacious peninsula of which it forms part, and which Europeans continue to call Asia Minor; but soon passing these limits, it was vaguely extended through the boundless regions of the East, till it finally embraced entirely the largest of the three continents. On the other side, directly to the south, the Greeks first landed on the coast of Libya; and the name of Libya was by them applied to the entire continent. With the Romans, on the contrary, whose position and political relations attached them entirely to the district of Africa proper, in which Carthage is situated, the name of Africa soon prevailed over every other.

80. *These grand divisions of the ancient world* were already known to Herodotus; but he has astonished European readers in an extraordinary degree by the assertion, that Europe is longer and of greater extent than Asia and Africa united. The severe judgment of M. Gosselin pronounces such an assertion, made in the midst of the nations which carried on the most extensive navigation, to be a proof that they had not formed the least idea of the distance which their vessels sailed along the Mediterranean. Before pronouncing so severe a sentence we must consider attentively what, in the conception of Herodotus, was Europe, and what was Asia. He mentions two boundaries: one formed by the Black Sea and the Don, which, though it does not form a very appropriate boundary of a continent, continues still to prevail, being connected with the Northern Ocean by the mountain chain of the Urals. But in the other, which is that preferred by Herodotus, the Black Sea is continued by the Caspian; the boundary line being carried along the north of that sea, and thence indefinitely eastward. Taking Europe in this sense, we find it in the west co-extended with the opposite coast of Africa, which the ancients necessarily considered as marking the length of that continent, while, in the east, however far Asia might be prolonged, Europe was still regarded as co-extensive. With regard to the boundaries of Africa, too, there was an extreme want of precision. Our limit of the Isthmus of Suez is certainly the most accurate; but the ancients, who could not readily admit the notion of a continent bounded by any thing but water, attached themselves more to the Nile, and did not well know whether to consider Egypt as Asiatic or African.

SUBSECT. 1. *The Europe of Herodotus.*

81. *Scythia* was the extremity of Europe, beyond Greece, with which Herodotus appears to have been most familiar, and which, in fact, he knew better than almost any other ancient writer. This name, which became ultimately Asiatic, was restricted by him to the tracts that now form the southern provinces of the Russian empire. These regions were then, and in a great measure still are, possessed by the same description of rude Nomadic and pastoral people, who have always occupied the central plains of Asia. The attention of the historian was specially called to them by the rash and daring expedition of Darius into a region secured by its natural barriers, and the wandering and untamed character of its people, against every form of regular subjection. Darius, crossing the Hellespont, marched along the southern shore of the Euxine, reached the banks of the Volga, and after the fruitless labour of erecting there several fortresses, returned by a more inland route, in which Major Rennell even supposes him to have passed the site of Little Novogorod. The knowledge acquired by this expedition, however, did not enable Herodotus to avoid great errors in the delineation of European Scythia. He imbibed a most exaggerated idea of the dimensions of the Palus Mæotis, which he calls the "mother of the Euxine." This appears to have arisen chiefly from the false *orienting* of the side which faces Russia, and which is made to stretch almost due north, instead of west, while the sea itself is represented as forming the eastern boundary of that great space of four hundred miles square, within which Herodotus comprises Scythia. The southern boundary was formed by the Euxine, and the other two by the land, so that he does not connect it in any shape with the Northern Ocean.

82. *The details of this extensive region* are given by Herodotus with considerable accuracy. Of its rivers, after the Danube, which he ranks second to the Nile, he mentions the Tyres or Dneister, the Hypanis, or Bog (and even describes the close approach of these rivers to each other in the upper part of their course), the great channel of the Borysthenes, or Dnieper, and the Tanais or Don. Between the last he mentions several streams, the Panticapes, Hypacysis, and Gerilus, which not being recognized by modern geography, Major Rennell supposes to be creeks or branches of the greater rivers.

83. *Milesian colonies* had, by the active enterprise of that commercial people, been already formed even on these rude shores. One, called the port of the Borysthenes, is described as the centre of the trade of Scythia. On the banks of this great river dwelt a people, bearing the rare character of the *ploughing* Scythians, who renouncing the almost universal habits of their race, raised crops of grain in this fertile district, which still furnishes to the ports of Taganrog and Odessa those supplies, which render them the granary of the Mediterranean. The Milesians had also a colony established at the mouth of the Danube.

84. *The northern interior countries of Europe*, which lay beyond the limits of the Scythia explored by the expedition of Darius, were covered for Herodotus with a veil of dim obscurity. On the Scythian frontier, along the heads of the Dnieper and Borysthenes, he represents several nations; the Melanchleni, "men clothed in black;" the Androphagi, "men eaters;" the Neuri, "once a year converted into foxes." These Greek names, and partly fabulous attributes, show the very imperfect nature of the notices collected on the subject. The regions beyond the Danube are expressly stated to be occupied by nations to him unknown. Two

precious commodities, the amber from the coast of Prussia, and the tin of the Cassiterides, under which last name a vague idea of the British Islands seems to be included, communicated the knowledge, that there was a great ocean in the north, but without the means of ascertaining its extent and limits. On the east, however, as already observed, he had attached to Europe a vast extent of territory which has been entirely severed from it in subsequent systems. The expanse of northern and even middle Asia, which the ancients afterwards called Scythia, and which forms the modern Tartary, inhabited by races exactly similar to the Scythians already described, appeared to Herodotus decidedly European. It was bounded by the Phasis, the Caspian, the Aral (not distinctly recognised), and the Jaxartes. The Massagetæ, celebrated for their contest with Cyrus, gave name with Herodotus to all the wandering tribes in this eastern part of Europe; but they were afterwards merged into the prevailing appellation of Scythians.

SUBJECT. 2. *Asia of Herodotus.*

85. *Asia, according to the conception of it formed by Herodotus, will appear, from what has been said, to include only a small portion of the vast continent to which we assign that name. On the north it had the same seas and rivers just enumerated as the boundaries of eastern Europe; to the east it terminated with India; while, even to the south, a large portion of the desert tracts of Arabia were not yet believed to exist. When this great historian wrote, all the various kingdoms and petty states, into which, in the infancy of the world, Asia had been partitioned, were absorbed into one vast empire. The Persians claimed Asia as their own, and had distributed it into twenty-four satrapies, which have been illustrated in a very learned manner by Major Rennell. They included, with the exception of the northern part, which he considered as European, all of Asia that was known to the Greeks. In collecting therefore from Major Rennell's investigation the following table of those satrapies, we exhibit not only the outline of that great empire, but, with the somewhat dubious exception of a small part of Greece, the whole of the civilised world. The tribute paid in talents of silver will exhibit their relative wealth and importance.*

TABLE OF THE DIVISION OF ASIA INTO SATRAPIES.

	Talents.
1. Ionia, Magnesia, Caria, Æolia, Syria, Pamphylia (the whole west and south coast of Asia Minor)	400
2. Mysia, Lydia, &c. (the western interior)	500
3. Phrygia, Paphlagonia, Cappadocia, &c. (the south coast and the great interior table land of Asia Minor)	360
4. Cilicia (including part of Syria, and reaching to the Euphrates)	500
5. Phœnicia, Palestine, and Cyprus (which furnished also a third part of the naval force of the empire)	360
6. Egypt, including Cyrene and Barca (half of the tribute paid in grain)	1400
9. Babylon and Assyria, including Syria, and furnishing also 500 eunuchs	1000
8. Susiana, or Southern Persia	500
10. Media (Northern Persia)	450
11. The Caspians, Pontica, Pantimathi, and Daritæ (the Caucasian provinces of Persia)	200
18. The Matieni, Saspire, &c. (Aderbijan and the Armenian provinces)	200
13. Armenia	400
19. The Mosetes, Tibareni, Mosquæil, &c. (the Western Caucasus, Georgia, Mingrelia, as far as Trebisonde)	300
14. The Sangarians, Sarameans, &c. (Seistan, Caramania, Lar, and other territories along the Indian Ocean, and the eastern part of the Persian Gulf)	600
16. The Parthians, Choasmiens, Sogdians, and Arians (Khorassan, Herat, Candahar)	300
7. The Gandarii, the Dodicæ, &c. (Margiana, the country on the Murghab, between Khorassan and the Oxus)	170
12. Bactria (Balk)	360
15. The Sacæ and Caspiæ (Kaushkaur, Pamer, and other tracts of mountainous country about the head of the Oxus)	250
17. The Paricani and Ethiopians of Asia (Mekran, including, perhaps, Caubul, and the Delta of the Indus)	400
18. India, the largest of all, being 360 talents in gold, which amounts in silver to	4680

86. *Some outer tracts of this vast empire, not formed into regular satrapies, were privileged to furnish only presents, or gifts, under an appearance of voluntary homage. Among these were ranked the Persians proper, inhabiting the modern Fars, who obtained this distinction as the conquering people by whom the empire was originally founded. The Southern Arabians, and the Ethiopians above Egypt, derived the same immunity from the difficult access to those rude regions in which they dwelt. The Southern Arabians are said to have propitiated the favour of the great king by the present of a thousand talents of incense. The Colchians, and the occupants of the neighbouring heights of Caucasus, were also numbered among the "givers of gifts;" while the inhabitants of the northern parts of that great range, secure in their mountain fastnesses, are said to have cared very little about the mighty ruler of Persia.*

87. *These delineations of Asia display, upon the whole, a surprising accuracy and extent of knowledge; yet several remarkable errors occur with regard to points of which the investigation does not appear very difficult. Thus the breadth of Asia Minor was reduced almost a half; that between Babylon and the capital of Egypt was underrated at least a fourth; and the country between the Black Sea and the Caspian was placed in the same meridian with the Persian Gulf, while it is really four degrees to the westward. These errors are the more remarkable, as the distances, instead of being in excess, according to almost every other ancient example, fall short of the truth. The early travellers exaggerated every space over which they actually passed; but it sometimes happened that two points were approached from different quarters, and then united to each other by a hypothetical line, which, as men usually undervalue what they know nothing of, was made generally too small. It would not appear that any regular route had been formed across the high and rugged table land in the interior of Asia Minor from Cilicia to Trebisonde. These two points, being approached respectively along the southern and northern coasts of the peninsula, might be supposed nearer to each other than they really were. Egypt was approached through Syria and*

Palestine, and Babylon by descending the Euphrates; but the direct line between them lying across the Arabian desert, was scarcely known or frequented, and therefore became an ideal line in the view of Herodotus. The line from Armenia to the Persian Gulf was of course measured along the Euphrates, the general course of which was south; and as the ancients oriented all their lines to a cardinal point, they overlooked the gradual but constant bend which that river takes to the eastward.

88. *The ideas of Herodotus concerning the extent of Asia*, even including all that portion of it which he assigned to Europe, could not fail to be defective. He knew nothing of India beyond the Ganges, Thibet, China, Eastern Tartary, or Siberia, more than half the superficial extent of the continent. Even his notions concerning India were most imperfect. He describes it as bounded on the east by sand, stretching into an unknown and measureless desert. From this statement it clearly appears that his India comprehended merely the western part watered by the Indus and its five tributaries; he knew nothing of its widest and richest regions, the Gangetic provinces, Delhi, Bengal, and the Decan; large portions were also cut off from the southern coasts of Asia, which were supposed to be washed by an ocean called the Red or Erythrean Sea, without any distinction of the Persian Gulf, and very little of that which we now call the Red Sea.

SUBJECT. 3. *Africa of Herodotus.*

89. *In his enquiries respecting Africa*, Herodotus appears to have been equally diligent as concerning the other regions of the globe; but as he never proceeded beyond Egypt, and as the formidable barriers which nature opposes to him who attempts to penetrate the interior had been very imperfectly overcome, much in what he collected is obscured with mystery or perplexed with conjecture.

90. *Egypt* is described with great accuracy, and under some features which no longer exist; for the Tanitic and Pelusiatic branches of the Nile, of which little more than the channels can now be traced, were then in full flow. It appears, however, that considerable confusion prevailed respecting the quarter of the world to which Egypt was to be adjudged. As water formed the basis of the division into continents, the sandy isthmus of Suez, believed to be broader than it really was, appeared very ill fitted to form such a limit. The Nile therefore, in the opinion of all the Greeks, was the boundary of the continents: all to the east was Arabia; all to the west Libya; but a difficulty here arose in fixing the lot of Egypt itself. The Greeks, it appears, considered nothing as Egypt beyond the Delta; but this opinion is ridiculed by Herodotus, who observes, that in that case there must formerly have been no Egypt at all, since this its lower branch was evidently produced by the gradual alluvial depositions of the Nile. He contends reasonably, that all the banks of the Nile as far up as Elephantina, which was inhabited by Egyptians, was clearly Egypt. He accuses the Greeks of referring the Delta, or their Egypt, neither to Asia nor Libya. If we rightly understand his own idea, it is that the middle or Sebennytic branch was the proper point of division between those continents.

91. *In tracing the Nile above Egypt*, Herodotus states a line of two months' journey, partly along the banks, partly in boats which were dragged by ropes along the current through the rocky channel. At the end of this journey they came to Meroe, the capital of Ethiopia above Egypt, an ancient and celebrated kingdom, whose monuments were viewed with almost religious veneration, and whose monarchs had repeatedly conquered Egypt and founded dynasties. This Meroe we suspect to be Merawe, capital of the Sheygya kingdom, and including probably within its sway Dongola, situated on the opposite part of that winding course which the Nile here takes. Two months' journey farther was the country of the Egyptian exiles, a numerous body, who, having revolted from Psammeticus, sought the protection of the king of Ethiopia, and were cantoned by him in this remote district, which may be Sennaar, or rather, perhaps, the branch of the Bahr-el-Abiad opposite to it; for Herodotus shows his knowledge of this last stream by observing that it comes from the west.

92. *The long tract of desert to the west of Egypt* is also described by Herodotus in some detail, though apparently only from hearsay. The most conspicuous objects here are the oases, particularly that which contains the ancient and venerated temple of Jupiter Ammon. His statements, though on the whole in favour of Siwah, scarcely afford data sufficient to solve that difficult question. To the west he gives the names of a succession of wandering and pastoral tribes, such as still roam over these arid and sandy regions, deriving from the soil only the produce of the date tree. Many of them stand charged with morals peculiarly shameless and dissolute, the females indulging openly in the most irregular conduct, and making even a boast of the number of their paramours. Probably there may be scandal mixed in these very evil reports of the African ladies. An exception to this rude pastoral character existed on the coast of Cyrenaica, where the Greeks established flourishing colonies, which could be approached, however, only by the dangerous route of the Syrtis or quicksand, proverbial in ancient times as the scene of disastrous shipwreck.

93. *The Nasamones*, the most westerly as well as the most numerous of the wandering tribes, in general drove their herds along the sea coast, but in summer repaired to the Oasis of Ægila (Augila) to collect the dates produced in that district. A tribe among this people were called the Psylli, or devourers of serpents; and in fact appear to have a peculiar power of charming those noxious reptiles with which their deserts abound. Within their borders, on the side of Cyrene, where verdure first began to adorn the waste, Herodotus has fixed the fabled site of the Hesperian gardens.

94. *The Garamantes*, to the south-west of Augila, and the *Nasamones*, are represented by our historian as inhabitants of a region infested by wild beasts, and of a timid character, flying the view and intercourse

of other men, destitute of arms, and unacquainted with war. These characters do not apply to the people of modern Fezzan, which, however, is undoubtedly the tract pointed out. To the north-west were the Gindanes (the modern Gadamis), among whom the licence of public morals had risen to a greater height than among all the other wandering tribes of Libya. Still proceeding north-west, the traveller came to the lake Tritonis, celebrated in ancient fable as the birthplace of Minerva, who, according to one legend, was sprung from Neptune and the nymph of the lake. This lake forms the western limit of the long range of nomadic tribes. Beyond it, Herodotus gives us the Maxyes, who cultivated the ground. He had now reached that fine range of territory belonging to Carthage, stretching along the coast, watered and enriched by streams from the Atlas. It is very remarkable, however, that he should pass by entirely that mighty and celebrated state, which was not only the most powerful in Africa, but was also the centre of industry and commerce with respect to the ancient world. Major Rennell has suspected that this arose from a national feeling of enmity on account of their alliance with the Persians; but when we consider that no such feeling has prevented the fullest account from being given of the Persians themselves, it can scarcely be supposed that the being merely friends to the Persians would exclude so great a people from his notice. It seems really very difficult to conjecture his motive, unless, according to the suggestion of a learned friend, we suppose that Herodotus, writing almost entirely to illustrate what was obscure, or communicate knowledge on points respecting which the world were in ignorance, might think it superfluous to describe what must have been well known to the bulk of his readers, for the same reason that he has given no regular description of Greece. In reference to the transactions of this people with other nations, he takes repeated occasion to mention them, so that the omission could not arise from absolute ignorance.

95. *Atlas and the desert border behind it* next engages the attention of our historian; a tract reaching as far as the straits, which he calls the *high forehead* of Africa. He describes Atlas as a long and lofty range, whose highest pinnacles are wrapped in perpetual clouds; and he ascribes to the natives the origin of the belief adopted by the Greeks, which made it the pillar of heaven. Even in this extreme boundary of the continent, he mentions some peculiarities that really exist: — the enormous size and formidable character of the serpent tribe; oxen with large and crooked horns; houses of salt which would melt away if a single shower were to interrupt the continued drought. When he begins, however, to speak of people with horses' heads, and others without heads at all, it is time to take our leave; though some learned writers suppose this to be a mere exaggerated description of some animals of the desert. We must still follow him, however, to the western coast beyond the straits, where the Carthaginians, he was informed, carried on trade with the natives in a peculiar manner. The parties did not see each other, but after a signal made by smoke, one laid down his proffer, went away, and left room for the other to do the same; when the first came, and either accepted or rejected the bargain, till the terms were adjusted. There have been reports in various quarters of this mode of traffic, but all, we suspect, exaggerated representations of the timid manner in which civilised traders made their approaches to those savage people who possessed any valuable commodities. The product sought upon this shore was gold: and, as it does not exist in any latitude north of the Senegal, Major Rennell concludes that the trade of Carthage extended to that distant river. A sceptic might surmise that the gold was brought across the desert to the coast of Barbary; yet, considering the formidable character of this desert, it seems doubtful if at so early a period a commercial route across it could have been opened.

96. *The interior of Africa* could not fail deeply to attract the curiosity of Herodotus. The part already noticed as described by him forms only a belt along its northern coast, and includes none of the vast inland tracts. On this subject, however, he has only one tale to tell. Several Nasamonian youths of distinction, seized with that desire to penetrate the continent which has prevailed throughout all ages, departed on an expedition to the southward. They traversed three successive belts; first, the cultivated, or at least verdant and inhabited tract along the sea shore; then, another occupied only by wild beasts; and, lastly, a region arid and desolate. Here, while plucking some fruits, they were surprised by some men of small stature, who carried them by the way of very great lakes, to a city inhabited by black inhabitants, and situated on a large river flowing from west to east. This river Herodotus, naturally enough, judges to be the Nile. Major Rennell conceives it to be probably the river of Tombuctoo, which Europeans call the Niger; but we think, since the late discoveries, there can scarcely be any hesitation in fixing it as the Yeou, the river which rolls through Bornou, while the Tchad may be identified with the great lakes along which the expedition was conducted.

CHAP. IV.

FIRST ALEXANDRIAN SCHOOL. ERATOSTHENES AND STRABO.

SECT. I. *The Expedition of Alexander.*

97. *The geography of the Greeks* became little more than a topographical delineation of military routes after the intestine wars in which they were involved caused them to lose sight of the more distant regions of the earth. Besides, as they never cultivated mathematical science with any care or to any extent, they had not the power of arranging even these limited materials into a systematic form.

98. *The expedition of Alexander* gave a much greater degree of expansion to the human mind. That monarch transferred the seat of war into the Persian empire, and carried his victorious arms into the remotest regions of the East. Whatever might be the faults and follies with which his career was stained, it cannot be denied that an enlightened curiosity animated all his proceedings. Wherever he went, he was accompanied by skilful surveyors, Diognetus and Bæton, who measured the length and direction of every route over which the army passed. Alexander himself carefully inspected these itineraries, employed all practicable means for obtaining the best materials, and his letters are even quoted by Pliny as authorities for many geographical statements. These itineraries are said to have been afterwards published by Bæton, under the title of "the Marches of Alexander." From the defective state of the science, however, which that prince could not remedy, all these materials were necessarily imperfect. They could include nothing beyond mechanical measurement, nor is there any record, throughout this long career, of a single attempt to fix the position of any spot by celestial observation. Imperfect as they were, however, these documents did not the less form a completely new era in geographical science. After the death of Alexander, they passed through the hands of Seleucus into those of Ptolemy Philadelphus, who spared no efforts to render Alexandria the greatest seat of learning and science in the ancient world; and among the sciences there cultivated, geography and astronomy held the most distinguished place.

99. *The progress of Alexander* led him at first through Syria, Egypt, and Persia, but did not bring the Greeks to the knowledge of any countries, of whose existence and limits they were not already fully apprised. But after he began the pursuit of Bessus, who had carried off Darius into Bactriana, his march became a sort of exploratory route. In his vain pursuit of the Scythian armies he reached the banks of the Jaxartes, though he did not fully trace the course either of that river or of the Oxus. On his way thence to India, he had to penetrate the narrow passes overhung by the snowy ramparts of the Hindoo Coosh, and, with much difficulty and many hardships to his troops, learned to appreciate the magnitude of that great inland barrier of Asia. In India, Alexander could not penetrate beyond the region watered by the five rivers. Yet he did not consider it as the boundary of the earth; he learned the existence and beauty of the fine regions on the Ganges, whither he in vain attempted to persuade his fatigued and refractory troops to follow him. He consoled himself by conveying his army in pomp down the Indus, to view the entrance of that great stream into the ocean, and with instructions, as we have already seen, to trace the shores of Asia round the Persian Gulf. He himself, upon very bad information, undertook to lead back his army through Gedrosia and Caramania, the greater part of which he found, as modern travellers have done, to be a desert of the most dreary and formidable character, in which his army was with difficulty saved from total destruction.

SECT. II. *Expedition of Seleucus.*

100. *Seleucus*, on the partition of the empire of Alexander, succeeded to the dominion of Syria and the East. Neither that prince nor his successors were either learned or patrons of learning; but as the owner of extensive dominions, and aiming at farther conquest, he cherished the natural wish to be acquainted with what he possessed or hoped to obtain. He employed his admiral, Patrocles, to make a survey of the Caspian Sea, which had not entered into the line of Alexander's route; but the information gained by this voyage must, as we shall see, have been far from complete. It would also seem as if he had employed the same admiral in an attempt to circumnavigate Asia; but the assertion which obtained credit in that age, that he had sailed round from India to the Caspian, sufficiently attests the failure of the enterprise. Seleucus, also, finding, probably, that the inroad of Alexander into India had been of very transient result, undertook a military expedition, the details of which are little known, and which enabled him to establish no permanent footing in the country; but he collected some further materials for the geographer, and the record of his marches appears to have been of important service to Pliny. He sent also an embassy under Megasthenes to Palibothra, capital of the great Indian kingdom situated on the Ganges, from which the ancients derived a more accurate knowledge of these eastern parts of the world than they had previously possessed.

SECT. III.—*Eratosthenes.*

101. *Eratosthenes* at length succeeded in reducing geography to a system under the patronage of the Ptolemies, which gave him access to all the materials collected by Alexander, his generals, and successors, and to the immense mass of documents assembled in the Alexandrian library. The astronomical observations made in this school were now sufficient to prove the globular form of the earth. Eratosthenes, proceeding upon this principle, made it his study to adjust to it all the known features of the globe. He did not, however, attend to the grand original divisions of the equator, the pole, or even the tropics. The line which formed the basis of his geography, and generally of that of the Alexandrian school, was a parallel drawn across the Mediterranean, and thence prolonged through Asia. It was formed in a very rough manner, upon no actual observation, and comprising all leading

positions which came nearly though not strictly within its sphere. It was called generally, the parallel of Rhodes. The most westerly point was the Sacred Cape of Iberia (Cape St. Vincent), after which followed the "Strait of the Pillars" (of Hercules). The next point was the Strait of Sicily, erroneously considered to be under the same meridian with Rome and Carthage. Then came Rhodes, the centre of the line. Issus, celebrated as the site of the victory of Alexander, was with little difficulty brought within the limit. Next followed the somewhat doubtful position of the Caspian gates, and the line was extended along the chain of Mount Taurus, supposed to divide Asia into two parts, till it terminated at the remote city of Thinæ, situated on the eastern ocean. This entire length of the habitable world, as it was called, amounted to about 70,000 stadia, or, according to his estimate, one hundred degrees, not quite a third of the circuit of the globe.

102. *In determining a meridian to exhibit his breadth of the habitable world*, Eratosthenes laboured under still greater difficulties. On the extreme south was "the limit of the habitable earth;" for, according to this school, a certain tract around the equator was, from the excess of heat, unfit for human habitation. The uninhabitable zone was supposed to extend 8,300 stadia, or about twelve degrees to the north of the equator. Under the next parallel were included the "Isle of the Exiles," in or near Sennaar, the cinnamon-bearing region, which appears to be Berbera, and Taproban, or Ceylon. Next come Meroe, the capital of Ethiopia, which was supposed, though with great error, to correspond as to latitude with the southern extremity of India: thence descending the Nile the geographer marks the celebrated position of Syene, which was concluded to be immediately under the tropic, since there was a well, in the depth of which at noon-day, at the precise time of the vernal equinox, the disk of the sun was seen reflected entire. The observation was very nearly correct. Next came Alexandria, of which, as the centre of all these observations, the position as to latitude was very closely approximated. Then followed Rhodes in the centre of the great parallel already described as exhibiting the length of the habitable globe. Continuing northward, though not upon the same line, were found the Hellespont, Byzantium, the mouth of the Borysthenes, and passing over the vast obscurely-known tracts of Germany, Gaul, and Britain, the farthest Thule, which, on the report of Pytheas, Eratosthenes regarded as the extreme northern boundary of the earth. As the same authority placed Thule under the Arctic circle, or at sixty-six degrees of latitude, the interval between that position and the limit of the habitable earth on the side of the equator amounted to about forty-four degrees, or according to his estimate 38,000 stadia, which formed thus the supposed breadth from north to south of the habitable earth.

SECT. IV.—*Hipparchus.*

103. *Hipparchus*, carrying still farther the system adopted by Eratosthenes, subjected the whole science of geography to astronomical principles. His labours in numbering the stars, and arranging them according to their place in the heavens, were such as appeared marvellous to the ancients, and are esteemed by Pliny as achievements that would have been arduous even for a god. In this career, however, he had been preceded by Timocharis and Aristillus, who, more than a century before, had made some observations which paved the way for the present extended discoveries. Hipparchus appears to have first conceived the idea of transferring the observed latitudes and longitudes of the stars to their corresponding places on the earth's surface, thus fixing the latter with a precision which no itinerary measurements could ever attain. He made a considerable number of observations of latitude, in addition to the very few previously existing, and he pointed out the mode in which the longitudes might be ascertained by observing the eclipses of the sun and moon. It does not appear to what extent he carried the difficult operations requisite for this investigation; but he is said to have calculated the eclipses for six hundred years, including the moments of their appearance at different places; a performance which seems to indicate a knowledge of their astronomical position. Thus Hipparchus distinctly perceived all the principles upon which an accurate system of geography might be founded, and made some progress in their application; but these important principles, like others which were beyond the comprehension of the age in which they were made, remained for a long time dormant or misapplied, and were not brought into full practical application until a much more advanced period in the progress of science.

SECT. V. *The world according to Eratosthenes and Strabo.*

104. *The application to the different parts of the earth's surface* of the principles according to which the globe was to be delineated, formed a task still more arduous than that of the first establishment of those principles. The longitudes and latitudes of the ancients are both erroneous; more especially the longitudes, to which astronomical observation was never very extensively applied; hence it is not wonderful that the errors should be great; but the regular and rapid manner in which they accumulate appears very surprising. They begin from the Sacred Cape of Iberia (Cape St. Vincent), which the ancients made their first meridian, and continue regularly increasing as we proceed eastward.

To the pillars of Hercules were assigned more than two degrees beyond the truth; to Alexandria, nearly seven; to Issus, ten; to the Caspian gates, fourteen; to Pattalena, or the Delta of the Indus, twenty-three; to the mouth of the Ganges, nearly twenty-seven. M. Gosselin, by collecting these errors, has shown, that they must arise not from single defective observations, but from some general cause. To discover it, he has had recourse to a very bold and ingenious hypothesis. He supposes Eratosthenes to have had under his eye an early map, found, probably by Alexander or his generals, in some country of the East, where astronomical observation had been pursued with a degree of accuracy never attained among the Greeks. On this map he supposes the parts of the globe to have been correctly laid down, but on the principle of a plane map, where degrees were delineated as of equal length at all distances from the equator. This mode of graduation Eratosthenes is supposed to have misunderstood, and to have considered the map as formed on the more exact plan, which made the degrees on his great parallel to consist only of 555 stadia, instead of 700, their length on the equator. Dividing, therefore, the stadia on the map by 555 and not by 700, he brought out a number of degrees much above the truth, and always the more so as the space measured became greater. This conjecture is, doubtless, highly ingenious, and the application of it produces an approximation to the real positions which is somewhat surprising. At the same time, it does not seem very probable, that so perfect a school of geography as is here supposed should have so early existed; we know not well where its seat could have been; nor does this supposed excellence seem very consistent with the imperfect mode of graduation here supposed, and with the absence of any indication of the principle on which it was constructed. A more simple and probable solution seems to be, that the graduation was calculated from the itinerary measures reduced to degrees, at the rate adopted by Eratosthenes of 700 at the equator, and 555 upon his main parallel of Rhodes. We have already had occasion to observe, and the remark is found in the best ancient geographers, that merchants and travellers of that age gave an exaggerated report of all the distances over which they passed. The windings of the route, the hardships and obstacles encountered by them, the desire to magnify their own achievements, all concurred in inducing them to view and present this particular through an amplified medium. All the itineraries continued along the line upon which Eratosthenes measured his length of the habitable globe being thus unduly extended, the degrees calculated out of them were of course equally in excess; and this excess became always the greater in proportion to the length to which the line was protracted beyond its commencement at the Sacred Cape. The latitude of the principal places in and round the Mediterranean is in general not far from the truth, probably because it was determined by such rude observations as were within the compass of Greek science at that early period.

105. *In tracing the outline of the known world*, and especially of the continents, geographers still proceeded amid obscurity and doubt. This school had laid down the fundamental principle of a great circumambient ocean, embracing the entire circuit of the three continents. This idea, inherited from Homer, was doubtless supported by facts to a considerable extent; but its application to the world in general, and especially to the northern shores of Europe and Asia, was manifestly hypothetical. Eratosthenes, in comparing the magnitude of his known world, even under its exaggerated dimensions, with the general circumference of the earth, became sensible that only a third part of this last was filled up. He indulges in conjecture as to the contents of this vast unknown region, which, he observes, might either be supposed to consist of one great ocean, the whole of which he denominates the Atlantic, or of lands and islands which might be discovered in sailing to the eastward. With a degree of caution, however, not very common in that age, he declines to give any decisive opinion on this question.—The system of Eratosthenes may now be considered in regard to Europe, Asia, and Africa.

SUBSECT. 1. *Europe.* (Fig. 6.)

106. *The imperfection of ancient geography* is often conspicuous with respect to countries which were very near and familiar. In regard to the very centre of the Mediterranean, Eratosthenes committed a capital error. Following the propensity to include all the leading positions under some one line to which they approximate, he placed in the same meridian Rome, the Sicilian strait (that of Messina), and Carthage. The mistake with regard to the first and last of these points did not much exceed a degree; but the middle point is nearly four degrees east from Rome, and five from Carthage. Such an error could not fail to produce others. M. Gosselin shows that it has led to a signal mistake respecting the

position of Sicily, as the geographer, in order to retain its relative position towards Carthage, necessarily represented its greatest length as from north to south, instead of from east to west. The promontory of Lilybæum, facing Carthage, became the southern instead of the western extremity of Sicily; while Cape Pachynum, instead of the southern, became the eastern. Sicily being thus projected so unreasonably towards the south, Carthage also was made to recede too far in the same direction; and the coast leading thither from the straits of Gibraltar was supposed to bend to the north instead of the south. The same erroneous process, placing Sicily too far west, enlarged beyond measure the eastern basin of the Mediterranean comprehended between it and Asia Minor. This deformity became still more serious from another application, to Alexandria and Rhodes, of the system of placing leading points under the same meridian. As the former error had made Sicily too far west, this made Rhodes too far east, and rendered the sea between these islands too large by at least a half.

107. *Strabo*, ever alive to the faults of his predecessors, detected the mistake of *Eratosthenes* with respect to the relative positions of Rome and Carthage. He has been far, however, from rectifying all the wrong positions established by his predecessor. He has left untouched the false orienting of Sicily, and all the errors dependent upon it. Both he and *Eratosthenes* describe Italy as extending from north to south, which, allowing for the early tendency to orient all lines towards a cardinal point, may be taken as a pretty fair representation. *M. Gosselin* has undertaken to show that such a direction would be inconsistent with the other data given by these geographers, in conformity to which Italy must stretch from east to west. Considering, however, the imperfect state of geographical delineation at that period, it seems going too far to follow each error into all its consequences, or to suppose that all the views given can be brought into complete harmony.

108. *The outline of the central and northern countries of Europe* drawn by these geographers is excessively vague. *Strabo* indeed makes some approach to accuracy in comparing the Spanish peninsula to a "hide spread out," or to a parallelogram. Various countries were by the ancients denominated from a fancied resemblance to some object in nature, nor are examples wanting in modern times. But the eastern side of this figure is formed by the Pyrenees, which are thus made to extend from north to south, to form the western boundary of Gaul, and to be parallel to the Rhine. Hence arises the greatest of all these errors; for Gaul is allowed to have on the ocean only one coast, which is that looking to the north, and every where opposite to Britain. *Strabo* treats with derision the report of *Pytheas*, that the *Calbium promontorium*, the extreme point of Brittany, looked to the west, and he represents vessels as sailing to Britain as readily from the mouth of the Loire and Garonne as from that of the Rhine and the Seine. Great as these errors are, we shall easily trace their origin in considering the sources whence the Greeks derived their information respecting these extremities of Europe. Whatever may have been the case with regard to the Carthaginians, it is evident that neither Greeks nor Romans ever navigated its exterior seas. *Pytheas* alone performed that daring voyage; but having no witnesses to bring in support of his relation, it was denounced as fabulous, in common with others made by early discoverers. The regular channel of communication was Marseilles. The merchandise of Britain being brought across the British channel to the mouths of the Rhine and the Seine, was conveyed down those rivers, and by land carriage to that great emporium of Gaul. Hence the geography of Gaul and Britain, in that age, was ruled entirely by Massylian ideas. From the causes stated, the Massylians had no communication with Britain unless by the northern coast of Gaul, and by routes directed from south to north through that country. Reasoning only from what they knew, they might soon arrive at the conclusion, that Gaul had only a northern coast, and might apply to it the whole of the erroneous system now described. The result of this system was, that the *Cassiterides*, Islands of Tin, in which term the Scilly islands were evidently blended with Cornwall, were made to approach to Spain, and came to be considered as much Spanish as British. So prevalent was this idea, that even afterwards, when the conquests of Rome had made known the wide separation between the two countries, the *Cassiterides* are found in some maps still attached to Spain, and at a little distance from Cape Ortegal.

109. *Britain, under this system*, was represented as a triangle, of which the base, or longest side, was that along the channel and opposite to Gaul. As the coast, after passing the two extremities of this line, begins on one side to bend inward towards the Bristol Channel, and on the other to the Thames, navigators then probably considered it as continuing in these directions till it came to a point, far short of its real termination. *Ierne* (Ireland) appears in dim obscurity. It is said to be situated four hundred miles north from the centre of Britain, under a climate so excessively cold that there could not possibly be any inhabited country nearer to the pole. If the four hundred miles be measured from the centre of the southern coast, and allowance be made for false orienting, it will not be found so very wide of the truth. The rest of the description was probably made out by confused ideas of Scotland, and particularly the bleak mountainous tracts in the north. *Eratosthenes*, indeed, has derived from *Pytheas* a knowledge of the far northern limit of Thule, and of its appendant islands, stretching towards the Arctic sea; but, as the proud scepticism of *Strabo* rejected this statement, he was thrown back upon the more imperfect information afforded by the merchants of Marseilles.

110. *The eastern shores of northern Europe* occasioned still more embarrassment to the Greeks. They had, in general, the idea of this continent having the sea for its boundary; but this seems mainly to rest upon the general vague belief of a circumambient ocean, and an understanding that Germany had on the north a maritime boundary, indicated by the amber brought from the shores of the Baltic. Here, too, *Pytheas*, either by personal investigation or by careful enquiry, had collected some particulars which if *Strabo* had not disdained, he would not have been left in such total darkness. After proceeding far along the German coast, that navigator, it is said, came to a great gulf (evidently the Baltic). He found *Basilia*, a very large island, the same which *Pliny* calls *Baltia*; being, in fact, the peninsula of Scandinavia, which, until it was circumnavigated, must have been regarded by navigators as an island. Then, it is said, he came to the Tanais,

which appears, no doubt, a very startling assertion; but we must remember that, in this school, the circumambient ocean was supposed to have a coast only a little north of the Euxine and the Caspian, and to communicate with these seas or gulfs (as they were supposed to be) by narrow straits, one of which was the Tanais, and the mouth of one of the great Baltic rivers might very easily be imagined to form the termination of this strait.

SUBSECT. 2. *Asia.* (Fig. 7. page 34.)

111. *The limits assigned to Asia*, already too small, were contracted by the geographers of the Alexandrian school, notwithstanding the additional sources of information which they possessed respecting that continent. This error arose partly from their theory of a surrounding ocean, and partly from their neglect of the important information obtained by Herodotus respecting the countries along the heads of the Euxine and Caspian. The expedition of Alexander, indeed, and the embassy of Megasthenes, made them acquainted with the Ganges, rolling eastward through the fine plain of Upper Hindostan. Seeing it pursue this direction to the utmost limit of the then known world, they were led to conclude that its course continued eastward, and that it fell into the eastern ocean, which formed, on that side, the boundary of the continent. Connecting this with the Caspian, the only northern Asiatic sea known to them, they drew a line from one to the other, by which they excluded nearly two thirds of the extent of Asia; the Birman empire, China, the greater part of Tartary, and the whole of Siberia. On the shore of the eastern ocean was placed Thinaë, evidently known only by vague rumour, and which they fixed at the extremity of the line measuring the length of the habitable globe. What may be the import of this mysterious name, and whether it be the capital of Siam or of China, is a discussion which will be better reserved until we come to the more precise notices of Ptolemy. One other grand feature was known to this school; the cape of the Coliaci or Cape Comorin; but conceiving the coast of Coromandel to follow the line of the Ganges, and, consequently, to verge towards the west, they made it several degrees more easterly than even Thinaë.

112. *Asia within and Asia beyond Taurus* were made the grand divisions of that continent. That great mountain chain arising in Asia Minor was supposed to be prolonged by those of the Elbruz, of Khorassan, and of Hindoo Coosh, which, in fact, there is much reason to believe, may form a chain nowhere wholly interrupted. Within Taurus were all the fertile, populous, and splendid kingdoms of Asia; Syria, Assyria, Babylon, Persia, Susiana, Ionia, Cilicia; beyond, were the ruder tracts of Scythia, Bactria, Sogdiana; and more westerly, the Caucasian territory, and the part of Asia Minor situated along the shore of the Black Sea.

SUBSECT. 3. *Africa.*

113. *In regard to Africa*, the knowledge of these geographers, though accurate in some respects, was extremely limited. They believed its boundary to be the sea; but this correct judgment proceeded rather from a casual coincidence with their theory of an encircling ocean, than from any actual knowledge; since Strabo rejected even the possibility of circumnavigation. This scepticism was founded upon the hypothesis of an uninhabitable torrid zone, which formed an essential part of the reigning system at this period. It is a belief manifestly African, founded on the observation of those vast and burning deserts, which extend indefinitely beyond the narrow inhabited stripe bordering on the Mediterranean. The Nile, then, being still considered as the eastern boundary, Africa became a sort of right-angled triangle, of which the two smaller sides were formed by that river and the Mediterranean, while the hypotenuse, or largest side, was the unexplored shore. It was upon the Nile that Eratosthenes measured the habitable world of Africa; yet he does not trace that river so high as Herodotus, his details reaching only between three and four hundred miles above Meroë. In these details, however, he is very accurate: on the eastern side, he represents it as receiving two great rivers, the Astapus and the Astaboras, the former of which flows from lakes in the south, and, when swelled by the summer rains, forms almost the main body of the Nile. He describes also the bend which the river makes in its passage through Nubia. The source, being imagined to exist in regions rendered inaccessible by extreme heat, could not be considered as within the reach of discovery. The idea, however, still prevailed, that it came from the west, and Strabo even mentions a report, that its source was in the remote region of Mauritania, south of the Atlas. This is the only statement made by geographers of this school, which can be considered as indicating any idea of the existence of the Niger.

CHAP. V.

ROMAN GEOGRAPHY.

114. *The Roman geographers* attained no proficiency in the mathematical branch of the science. M. Gosselin does not even hesitate to assert, that they remained always strangers to its very first elements. They made no attempt, therefore, to combine their materials into

one harmonious system, or to fix their positions with that strict accuracy, which astronomical observation alone can reach. Yet no nation employed greater diligence in the operations of practical survey. This was, indeed, absolutely requisite with a view to that incessant warfare in which they were engaged; they could not conquer the world without previously surveying it. Their geographical researches were, however, held strictly subservient to this ambitious design.

115. *Itineraries* were thus the only form in which the results of Roman investigation were presented. Vegetius informs us that when war was to be carried into any country, the first care was to procure a complete set of routes, and place them in the hands of the general. These itineraries, it is observed, ought, if possible, to contain, not merely the intervals, in paces and Roman miles, between one place and another, but the quality of the roads, the surrounding objects, mountains and rivers, delineated with the utmost possible precision. They were not only to be noted, but painted, that the commanders might not know merely, but see before their eyes, the route by which they were to proceed. The Romans became thus the surveyors as well as the conquerors of the world; and every new war in which they engaged, every new conquest which their arms achieved, produced a fresh accumulation of materials for the use of the geographer. Even after a country was subdued, the necessity of accurate survey did not cease. The empire was long held in a state of mere military occupation; camps formed at proper distances were connected by those excellent and durable roads, many of which remain to this day. An accurate acquaintance with the position and intervals of these camps, and the nature of the intervening territory, was essential to the maintenance of their dominion over the vast extent of their conquered countries. No sooner, therefore, had Julius Cæsar seated himself on the undisputed throne of the empire, than he caused a *senatus consultum* to be passed for a general measurement of the Roman world. This task, it is said, was intrusted to "the most prudent men, adorned with every endowment of philosophy." The east was assigned to Zenodoxus, the west to Theodotus, and the south to Polycletus. In the course of twenty-five years, as we are informed by Æthicus, the whole was completed. Julius Cæsar, however, did not long survive the commencement of this great work, which the civil wars probably suspended. It was apparently resumed and completed under the reign of Augustus and the ministry of his son-in-law Agrippa, to whom it appears, from Pliny, to have been afterwards ascribed. The exact principles upon which this grand measurement was conducted have nowhere been stated. The reform of the calendar, effected by Cæsar, seems to point out that some elements of astronomy existed among those with whom he consulted.

116. *Rome*, in the most flourishing era of its literature, produced two eminent geographers. Mela and Pliny.

SECT. I. *Mela.*

117. *The personal history* of this eminent geographer is a subject respecting which scarcely any particulars have transpired. From the allusions, however, in his own writings, to the conquest of Britain by Claudius as a recent event, made in those flattering terms which only a contemporary would have employed, it would appear that his work was written under the reign of that inglorious prince, and is, consequently, anterior to that of Pliny.

118. *Mela, in forming his system*, does not appear to have possessed those extensive measurements and itineraries, which were probably deposited in the imperial archives. Faithful, however, to the object of his treatise, "de situ orbis," he discovers very considerable anxiety to determine the position of the globe, and trace with accuracy its general outlines. He adopts the general principles of the school of Eratosthenes, incorporating into it the new features which had been afforded by Roman conquest. He does not appear, however, to have comprehended their idea of the globular form of the earth, nor is he very perspicuous in any thing that he says upon that subject. He begins — "All that, whatever it is, to which we give the name of the world and heaven, is one thing, and in one circuit embraces itself and all things;" vague and pompous expressions, to which no determinate idea can be attached. We find him, however, adopting in its fullest extent the belief of a circumambient ocean; and when he speaks of "the high earth in this middle part of it," and describes the sea as going under and washing round it, we are led to believe, that he viewed the earth as a sort of cone, or as a high mountain raised by its elevation above the abyss of waters. Having made a vague division of the world into east, west, and north, he distributed it into five zones, two temperate, one torrid, and two frigid. Only the first two were habitable; and that on the south was inaccessible to man, on account of the torrid regions intervening. According to this system, however, there was on that side another earth, inhabited by people, whom he calls

Fig. 8. SYSTEM OF MELA.

Antichthones, from their opposite position with respect to that part which we inhabit. The form and boundaries of the known and habitable earth are thus delineated: — The Mediterranean, with its branches of the Straits, the Euxine, and the Palus Mæotis; its great tributaries, the Nile and the Tanais; — these combine, in his conception, to form the grand line by which the universe is divided. The Mediterranean itself separates Europe from Africa; and these continents are bounded on the east, the former by the Tanais, the latter by the Nile; all beyond or to the east of these limits was Asia. (Fig. 8.)

119. In drawing the outline of Asia, Mela adheres very strictly to his Alexandrian models. He describes it as bounded by an ocean on every side except the western, where it confines with Africa and Europe. It presents, he says, a huge and perpetual front to the eastern ocean, its shores being occupied by the three farthest known nations, the Indians on the south, the Seres in the middle, and the Scythians on the north; but the territory of the Indians and Scythians is rendered in a great measure uninhabitable by the extremes of heat and cold. The limited extent of his accurate information, however, is apparent from the representation he gives of this ocean, as flowing directly north from the point of Colis (Cape Comorin), the Ganges flowing into it, and the Scythians occupying its shores as far as "the Caspian Bay." He even inclines to credit the report of an Indian vessel having been driven round by stress of weather to the coast of Germany. Thus he gave to Asia the same truncated form which it had received from the authors whom he followed; but he certainly rendered the dimensions of its eastern shore more ample, when he made it to consist, not of India only, but also of Serica and part of Scythia. With regard to the southern shores of Asia, they were known with sufficient accuracy, ever since the expedition of Alexander, and the voyage of Nearchus. He calls the Indian ocean the Red Sea, and recognises the Red Sea of modern geographers only under the name of the Arabian gulf; but this is plainly a mere nominal difference.

120. *Europe, as described by Mela*, extends from Tanais to Cadiz, and, with the exception of its eastern river-limit, is bounded every where by seas and oceans. Its leading feature is the Mediterranean, joined to the Euxine and the Palus Mœotis, which are considered only as prolongations of that sea; while the Ægean, the Ionian, and the Adriatic seas, form its three great gulfs. The eastern part he divides into the Tuscan and the Libyan seas. His delineation of the exterior coasts marks a great advance of knowledge. He assigns to Spain a northern, and to France a western coast of great extent, and adds that the Pyrenees, after separating France from Spain, enter the latter country and penetrate to its extremity, when they face the Atlantic. Here the whole chain of the Cantabrian mountains is considered, by no very strained meaning, as Pyrenean. In treating of these outer shores of Europe, and the "huge and infinite sea" on which they border, Mela relates, with exaggerating wonder, the phenomena, unknown to a Mediterranean people, of the tides, "that mighty movement by which the sea alternately advances and returns into itself, overflowing the lands, driving back mighty rivers, and sweeping away the strongest land animals." His speculations on the cause are singular; either the world is a great animal whose breathings excite in its breast these alternate movements; or it contains deep caves, into which the waters are alternately absorbed and ejected. He does, however, mention the theory which supposes them influenced by the moon, and remarks their correspondence with the movements of that body. In treating of the Cassiterides, or islands of tin, which include, as already observed, the Scilly Islands and Cornwall, he shows considerable perplexity, only observing that they are "in Celticis," indicating their close alliance with France. In regard to Britain itself, however, he confidently undertakes to give the world better information, in consequence of the victories of "the greatest of princes" over nations hitherto unsubdued and unknown; and he certainly makes a great progress beyond the imperfect notions of Strabo. He describes Britain as presenting two extensive oblique coasts, one looking towards France, the other towards Germany; the two forming a great angle nearly opposite to the mouth of the Rhine. The coasts then began to bend inwards, and form a triangle varied with numerous points and angles, and somewhat similar in form to Sicily. The country is described as flat, large, and fruitful, but contrary to what now obtains, more favourable to the support of flocks than of men. The natives were uncultivated, warlike, and ignorant of wealth; they were accustomed to paint their bodies, and to ride in chariots. Above Britain was Inverna (Ireland), nearly equal in size, and of an oblong form, its soil scarcely fit for the production of grain, but its pastures so luxuriant, that if the cattle were allowed to feed for more than a short period of the day, they died of repletion. The relative dimensions assigned to Britain and Ireland would seem to show that the former was known only in its southern part, yet the writer discovers himself not unacquainted with the Scottish islands. He mentions thirty Orcades, in which number the Shetland Islands are probably included.

121. *In proceeding to the east and north*, Germany is described by Mela as a region of great extent, intersected by many rivers, and covered in a great measure with woods and marshes. The inhabitants were tall and remarkable for courage and strength, continually exercised in war and hard labour, eating raw flesh, and clothed partly in the bark of trees. Passing the Vistula, we enter into Sarmatia, extending to the Danube, rather a vague limit, but the term is evidently meant to comprehend the greater part of modern Poland. The people are some stages in barbarism beyond even the Germans, having no cities or even settled abodes, and carrying their fierceness to such a pitch, that hunting and bending the bow were considered the best accomplishments of their females, no one of whom, the writer even asserts, could enter the matrimonial state till she had killed her man. On this shore he represents the Codanus Sinus, a great bay filled with large and small islands; nowhere presenting an expanse resembling a sea, but dispersed and scattered in narrow channels like rivers; a description very applicable to the entrance of the Baltic and the Danish islands. In common with all the ancients, however, Mela appears to have been ignorant of any thing like a continent on the other side of this great bay.

122. *The outline of Africa, drawn by this geographer*, sufficiently shows his limited range of information. This continent he views as a triangle, the greatest length of which, measured in his system from the Nile to the Atlantic, is considerably less than the length of Europe. Of this triangle, the Nile forms the base; and from thence the southern coast, or that of the Ethiopic ocean, continually approximates to the northern, till, beyond the Pillars of Hercules, it tapers almost to a point. The origin and course of the Nile are to Mela a subject of much speculation. One account, esteemed by him as tolerably credible (*aliquâ credibile*) identifies it with a great Ethiopian river, called in the language of the natives Nuchul; which, while all other rivers tend towards the ocean, alone flows eastward to the central region, and no one knows where it terminates; a striking coincidence with the actual observations of the moderns, respecting that celebrated stream denominated the Niger. Elsewhere, however, Mela propounds an hypothesis of a much more extraordinary character. He says, that if there be another earth (on the south of the equator), and *Antichthones* opposite to us, "it might not be departing too far from the truth" to suppose that the Nile arose in that earth, and reached our side of the globe by a channel beneath the ocean. Thus it would naturally swell during the summer solstice, which, on the side of the world from which it came, was the season of winter. Bertius and Vincent, however, have perhaps dealt too hardly with the author, in embodying this wild conception into a map, and giving it to the world as the system of Mela, who mentions it merely as a conjecture. The lower part of the course of the Nile he describes with less accuracy than Strabo, the two channels of the Astapus and Astaboras being made branches of the Nile itself, first separating and then re-uniting. His ignorance respecting even the shores of the Red Sea is proved by their being filled with poetical wonders; the pigmies waging their ancient war with the cranes; the phoenix, after a life of four hundred years, dying, and reviving from its ashes. Proceeding to the interior and remoter shores of Ethiopia, he finds always new wonders, sphynxes, birds with horns, flying horses. He refers to the voyages of Hanno and of Eudoxus, to whom he ascribes a variety of fables, by which the reputation of that navigator has been much and perhaps unjustly tarnished; lastly, he comes to the Fortunate Islands, of which the soil produces all things spontaneously, and the fountains are possessed of miraculous virtues. In short, every thing that Mela says of Africa beyond the mere Mediterranean coast betrays a remarkable ignorance of the mysteries of that continent.

SECTION II. *Pliny.*

123. *Pliny*, the most learned of the Roman writers, devotes two books of his extensive work on natural history to a system of geography. He appears to have possessed a greater store of authentic materials than any former writer. From his intimate connection with the imperial family, and with many of the most eminent commanders, all the military measurements, as well as the general survey of the Roman empire, were placed at his disposal. He has introduced, therefore, a multitude of itinerary details, which are generally very accurate and valuable. But he employs no astronomical elements, and appears to have taken no pains to construct a regular system. All the general ideas which we can trace in his delineation appear to be founded on the same basis with those of Mela.

124. *Pliny begins with Europe*, which he considers as by far the most beautiful and fruitful of the three quarters of the globe; and he applauds the opinion of those who consider it not merely as a third, but as a half of the whole globe, separated from the other half by the Tanais and the Mediterranean. This capital error, however, will not appear so surprising, when we consider that the regions here compared with Europe were Asia terminated by the Ganges and the Jaxartes, and Africa extending only a few hundred miles inland from the Mediterranean. Europe had been computed by Agrippa at 3440 miles in length, by Polybius at only 2440; which last dimension is nearly correct, though M. Gosselin contends, that as it does not agree with the sum of his particular distances, it must have been derived from an earlier and purer source. Pliny discovers a clear

conception of the form of Spain, drawing the Pyrenees not from south to north, but from south-east to north-west, and observing that Spain, "where it begins from them, is narrower than France, and even than itself." The position of Britain in the map of Europe is very fairly given; though, to enumerate Spain, with France and Germany, among the countries to which it is opposite, partakes too much of antiquated theories. He states the belief of Agrippa that Britain was eight hundred miles in length, and three hundred in breadth; Ireland the same in breadth, but shorter by two hundred miles; which is a tolerable estimate, the last particular excepted. His disposal of the islands around Britain is not a little confused. He mentions the Orkneys, seven *Æmodæ*, and thirty *Ehudæ*, but without showing any precise idea of how they stand. Not only the Isle of Man, but that of Wight also, is placed between England and Ireland. He commits also a remarkable error when he mentions *Cassiterim* or *Cattiterim*, where tin is produced, as an island at the distance of six days' sail from Britain. To the remotest point, Thule, he assigns the attributes of a region beneath the Arctic circle, having only one day and one night in the year; and only a day's sail from the *Cronium* or *Concrete Sea*. Here, also, he mentions reports of other islands, *Scandia*, *Bergos* (*Bergen*), *Nerigon*, which have intercourse with Thule. These features evidently belong to the coast of Norway.

125. *In describing the north of Europe*, Pliny begins from the northern shores of the Euxine, and *Palus Mæotis*. The latter receives the *Tanais*, flowing from the *Riphean Mountains*, and forming the boundary of Europe. Beyond that celebrated and demi-fabulous range, he still finds the *Hyperboreans*, a people screened from every noxious blast, leading a happy life exempt from old age, sickness, discord, and grief; till at length, satiated with felicity, they throw themselves from a rock into the sea. These fables are, however, qualified with the saving clause, "if we are to believe them," which shows that the faith of Pliny was not implicit. The shores of the ocean, he confesses, are "marked by uncertainty." On the authority, however, of *Xenophon Lampsacenus* and of *Pytheas*, he reports *Basilia* or *Baltia* as an island of immense magnitude, three days' journey from the *Scythian coast*. Proceeding westward, he comes to the *Cimbric Chersonese*, and opposite to it another island, *Scandinavia*, of unexplored magnitude, but which was by many described as forming quite another world. Thus *Baltia* and *Scandinavia*, approached from different points, are considered as two distinct insular territories, the vast extent of which, however, appears to be better apprehended by Pliny than by any other ancient writer.

126. *Asia, in Pliny*, is delineated according to the general ideas of *Strabo* and *Mela*. The *Caspian* or *Hyrceanian Sea* is a gulf opening into the northern or *Scythian ocean*, which is in communication with that called *Seric* or *Oriental*. Pliny seems to have fuller information of the grandeur and wealth of *India* than any of his predecessors. Its inhabitants and its cities were innumerable, and it was reported on good authority to form a third of the whole world. It enjoyed gentle breezes, two summers, two harvests, one before, another after the periodical winds. Blessed with these advantages, this happy people were never known to emigrate beyond their own territories. He describes the marches of *Alexander*, from the measurements of *Diognetus* and *Bæton*, and where these fail, he continues them by those of *Seleucus*, and by the embassy of *Megasthenes*, as far as the mouth of the *Ganges*. These itineraries seem very good. In treating of *Taprobane*, he observes, that it had been believed by some to be an opposite continent or earth, but that the enquiries of *Alexander* had clearly proved it to be an island. His report, however, that the country of the *Seres* was seen from it, implies a most inadequate and erroneous conception of the eastern coasts of *Asia*.

127. *The Africa of Pliny* does not differ in its general outline from that of *Mela*. His access, however, to the archives of the empire, and his acquaintance with some of the Roman generals, enabled him to give new details as to some of its most interior tracts. The region of *Atlas* had been first penetrated in the reign of *Claudius*, by *Ædemon*, an adherent of the extinct family of the *Ptolemies*, who sought refuge there. *Suetonius Paulinus*, with whom Pliny had conversed, found it of immense height, covered with snow even in summer; on one side rising from the sands, rough, horrid, and bare; on the other, covered with thick groves of unknown species of trees, and sparkling with fountains. An account is given of a voyage along the western coast, which *Polybius* had made by order of *Scipio*. Only the names of the places and the distances are given. The former coincide in a great measure with those of *Hanno*; and if *Polybius* was right in this coincidence, his report tends much to confirm *M. Gosselin's* view of the limited extent of *Hanno's* discoveries. In the time of *Vespasian*, another expedition, under *Cornelius Balbus*, penetrated into and conquered *Garama* (*Germa*), and *Cydamus* (*Gadamis*). The Romans here beheld with surprise houses built of salt, and on digging to a small depth, water sprung out of the sand. A number of names of conquered places are here given, which it is difficult to recognise; for it seems too hasty to identify *Boin* with *Bornou*.

128. *A theory of the course of the Niger* was formed by Pliny from these materials with considerable pains, but very imperfect success. Its source, according to king *Juba*, existed in *Mauritania*, and it is even said to have been found by *Suetonius Paulinus* after a few days' march to the south of the *Atlas*. The *Niger* springs here from a lake; but soon, indignant at flowing through sandy and squalid tracts, it passes under ground for several days, and emerges into another lake of *Mauritania*. After a circuit, however, of some extent, it again disappears, and having pursued a subterranean course of twenty days, re-appears, dividing *Africa* from *Ethiopia*. At last, in its passage through *Ethiopia* itself, it assumes the character of the *Nile*, first in two channels, *Astusapes* and *Astaboras*, enclosing the island of *Meroe*, and afterwards uniting to form the entire and proper *Nile*. This wild and absurd detail evidently includes the course of several rivers belonging to different and widely remote regions of *Africa*. It may even be doubted, if any part belongs to what by moderns has been considered the *Niger*. It seems very probable, however, that the middle part, which divides *Africa* from *Ethiopia*, has been suggested by the river of *Bornou*, or the *Yeou*, as it has been called by our recent discoverers.

SECT. III. *Itineraries. — Peutingerian Table.*

129. *Of the itineraries* composed by the masters of the world, and employed by them as an instrument in its conquest, some fragments yet remain. The most memorable is that which bears the name of *Antoninus*. It has been ascribed by some to *Severus*, by others to *Theodosius*, and in fact contains many particulars which could not have been written prior to the era of the last sovereigns; but it seems probable that there were successive editions, with such amendments and alterations as time suggested. It is a mere skeleton road-book, with nothing but the names of places and their distance from each other. The same may be said of the *Jerusalem Itinerary*, exhibiting in great detail the route from *Bordeaux* to that holy city.

130. *The Peutingerian Table* (the Italian portion of which is exhibited in fig. 9. p. 40.) is a more remarkable monument, and may be considered, probably, as a specimen of the "painted roads" of the ancients. It forms a map of the world, constructed, however, on the most novel and peculiar principles. Its dimensions being twenty feet in length and one in breadth, an idea

may be formed of the correctness with which the proportion of the different parts is exhibited. The high road which traversed the Roman empire in the general direction of east and west is made the first meridian, and to this every other part is subjected. The objects along this line are minutely and faithfully exhibited; of those lying to the north and south of it only some general notion can be conveyed: these are all represented, of course, most enormously extended in length and reduced in breadth.

CHAP. VI.

SECOND ALEXANDRIAN SCHOOL.

131. *Alexandria by her contributions to geography* supplied to a great extent the deficiencies of the Romans, who, amid the success with which they cultivated history and literature, never attained to any eminence in this science. That capital, even in its subject state, retained still the impulse received from the Ptolemies, and continued to be the second in magnitude, and the foremost in learning, of all in the empire. In the second century there was established, here and at Tyre, a geographical school, possessing more ample materials and resources than any that had hitherto existed. To the conquests and itineraries of Alexander were now added those of Rome, which, extending in a different direction, embraced many countries to the north and to the west, Gaul, Britain, Germany, Spain, and Mauritania, respecting which the Greeks had possessed only confused and imperfect notions. Thus a greater portion of the globe than at any former period was now united under one government, which, by a standing army and a regular system of laws, preserved the whole in peace and order. The terror of the Roman arms enabled travellers to penetrate with safety even beyond the limits of the empire. Lastly, the unbounded luxury of the great capitals, and above all of imperial Rome, enriched with the spoils of the globe, fired the enterprise of the merchant, who found his way into those remotest markets of the eastern world, the rich commodities of which had hitherto been either brought by caravans or found at intermediate stations.

132. *These enlarged materials were connected together* by a much more accurate and scientific arrangement than had been adopted under the school of Eratosthenes. The method suggested by Hipparchus of subjecting the whole of geography to astronomical principles, and of fixing the position of every spot upon the globe according to its longitude and latitude, was now attempted to be carried into full effect. The attempt, however, was made but in a very rude manner, and upon a very narrow basis of observation. Not only, therefore, did it present a very imperfect edition of the new system, but involved errors which caused it in some respects to retrograde even from the rude state to which it had been brought by the former school of Alexandria.

SECT. I. *Marinus of Tyre.*

133. *No Tyrian system of geography* has come down to us, notwithstanding the commercial greatness of its people at an early period. From the Hebrew writers we have accounts perhaps of nearly the whole of the distant countries with which the Tyrians held intercourse; but if those writers are supposed to have borrowed from them their ideas respecting the general structure and boundaries of the earth, geography among the early Phœnicians will not appear to have passed its infancy. As Tyre, however, even under the Roman empire, remained still the seat of an extensive commerce, some of her intelligent citizens availed themselves of the lights afforded by the learning of Alexandria, and applied them to the illustration of those subjects on which the greatness and prosperity of their city depended. If the merchants of Tyre had nothing left of that proud rule, and those monopolising profits, which enabled them to rival the pomp of princes, their commercial relations probably extended over a wider surface of the globe than ever. They seem to have been engaged in that vast caravan route which was opened from Byzantium across the whole interior of Asia, conducting the merchants by a journey of ten or eleven months to the Chinese frontier, whence they brought silk, the staple product of that great country. Collecting these enlarged materials, Marinus, a native of Tyre, sought to apply to them the astronomical principles of Hipparchus, and thus to arrange geography into a new and more accurate form.

134. *The works of Marinus* have perished, and are known to us only by the references and extracts of Ptolemy; but these are sufficient to show that his system partook largely of the imperfection of a first effort. Aware that the degree of longitude diminished as it receded from the equator, he yet did not attempt to express this difference by representing the meridians with curved lines approaching each other, although this had been already shown by Hipparchus to be the proper course. He made them parallel to each other, not at the equatorial distance, but at that which belonged to them at the meridian of Rhodes. Thus in the part of the globe which came into his immediate observation he avoided any material error; but the meridians, adjusted only to this latitude, became too near each other as they were carried southward, and too distant as they went northward. He fell into a still more pernicious error in adopting the geodesic measurement of Posidonius, according to which the circumference of the earth was made to consist of only 180,000 stadia, and consequently the degree to contain only 500 stadia. This short degree, being calculated out of the exaggerated itineraries upon which the maps of those days were constructed, enormously amplified all the dimensions of the globe. Marinus appears also to have admitted with excessive credulity the extravagant reports of the mer-

chants who had penetrated across the vast mountain and desert tracts in the east of Asia. The rugged and difficult character of the region, the circuitous route which they were frequently obliged to follow, and the obstacles often encountered from the rude inhabitants, caused this journey to occupy a much longer time than those performed through districts better known; and time, as already observed, was the element out of which the ancients were chiefly accustomed to calculate space. Ptolemy also accuses the merchants of vain-glorious propensities, which led them to magnify beyond truth the extent and vastness of the regions which they traversed. Hence the great line upon which Marinus measured the length of the habitable globe, instead of one hundred and twenty-nine degrees given to it in the measurement of Eratosthenes, is swelled out to two hundred and twenty-five degrees, not much less than two-thirds of the globe; whereas the actual length, placing Thinae even at the eastern extremity of China, is not much more than one third. The exaggeration is enormous chiefly with respect to the country beyond India, which is made to comprise one hundred degrees. This being probably a new route opened through the Himalieh, and across the vast deserts of Eastern Tartary, had been affected by all the sources of amplification in a remarkable degree.

SECT. II. *Ptolemy.*

135. *Ptolemy*, the last and greatest of the geographers of antiquity, and equally illustrious as an astronomer, instituted a complete reform of the science, and undertook to purify it from all the false elements with which it had been alloyed. The principles, in fact, which he adopted were strictly correct; for though, as an astronomer, his theory of the universe was substantially false, yet, in admitting its globular form, and the revolution of the heavenly bodies, he admitted all the elements which were requisite for the less lofty sphere of earthly delineation. He adopted the system of Hipparchus in its utmost extent, subjecting every spot on the known globe to astronomical data, and constructing his tables, never according to itinerary distance, but according to the supposed latitude and longitude of each place. He saw and corrected the error of Marinus in making the degrees of longitude equal under every latitude. Thus, though Ptolemy did not actually introduce any new principle into geography, he was the first who combined together all the sound views of his predecessors, and formed out of them a just and harmonious delineation. Yet he was far from reaching his aim of forming a perfect system. He still retained the erroneous measurement of the degree formed by Posidonius, and of which Marinus had made so unfortunate a use. Hence, while he felt the extravagance of the distances assigned by his predecessor, in consequence of the adoption of the degree of 500 stadia, he extricated himself but partially from the same error. All his longitudes, extended along the length of the known world, present a similar accumulation of errors, only somewhat diminished in amount. These errors, beginning from Cape St. Vincent, constantly increase till, in India, they amount to upwards of forty degrees. M. Gosselin has even accused him of an error which, as he justly observes, would mark a strange departure from every principle, and a neglect of what ought to be the first care of a geographer. This consists in giving to his degrees of latitude a different dimension from that of the degrees of longitude, and retaining, with regard to the former, Eratosthenes's standard of 700 stadia. I suspect, however, that M. Gosselin has been somewhat precipitate in advancing so serious a charge against the first geographer of antiquity. The ground on which he proceeds seems to be, that while Ptolemy has changed materially all the longitudes of Eratosthenes, the latitudes along the great line continue unaltered and generally correct. The real cause of this, however, appears to be, that the latitudes of Rhodes and several other leading points of this great line were determined by

observations which, though not perfect, at least approached to the truth, while the longitudes were calculated merely out of the itineraries. This central line, therefore, bisecting the breadth of the known world, was fixed upon sound data, and the errors could accumulate only to the north and south of it. In fact, we shall find that they did accumulate as rapidly as in the longitudes, when the sphere of observation was passed, which was bounded by Syene on the south, Marseilles and Byzantium on the north. The mouth of the Seine is placed one degree too far north; that of the Rhine, nearly two degrees; that of the Elbe, more than two degrees; York is three degrees; and the farther accumulation is only prevented by that singular conformation which we shall find given by Ptolemy to the northern part of Britain. To the south, again, Axum is placed three degrees too far south; Cape Aromata (Guurdafui), nearly six degrees; and, as M. Gosselin will surely admit, from that point the errors continually become greater. Thus it appears, that as soon as Ptolemy quits the sphere of observation, his latitudes are calculated exactly as his longitudes, out of itineraries, and exhibit the same accumulation of errors.

136. *The manuscripts of Ptolemy* are clearly shown by M. Gosselin to have reached us in a very imperfect state. In collating with care the different editions, that learned writer has found a greater number of variations than in those of almost any other ancient writer. These variations were of course very likely to occur in copying cyphers where there was no connection of sense to check the copyist. The manuscripts and the maps appear to have been copied by different hands, holding no communication with each other; and accordingly these two parts of the same work do not, in many instances, correspond. Lastly, the work of Ptolemy appears, for several centuries, to have been carried about as a guide by mariners and travellers, who, wherever they found any feature which did not agree with their observations, altered the writing or the map accordingly. This process appears in the numerous variations of the Latin copies with regard to the western part of the Mediterranean, and of the Greek with regard to the eastern. The alterations thus made would often, and indeed, most generally, be improvements; but the great discrepancies which they introduced into the different copies, must have greatly bewildered the public.

137. *In delineating the geographical system of Ptolemy*, we can only consider the general outline, which is pretty much the same in all the editions. Ptolemy begins with rejecting the theory of his predecessors, from Homer to Strabo downwards, who represent the whole earth as enclosed by a circumambient ocean. Mercantile caravans, especially in the east of Asia, had now proceeded considerably beyond the line of coast which, according to the last school, had marked the eastern bounding ocean. They had passed that line without reaching the distant corresponding one by which the Pacific and Arctic seas were actually drawn around this vast continent. The eastern Atlantic, and the Northern Oceans were, therefore, effaced from the delineation of Asia, and an indefinite expanse of *terra incognita* (unknown land) was substituted as the boundary of the world. This proceeding must certainly be considered as more precise and philosophical than the gratuitous theoretical one for which it was substituted. Men, however, seldom know exactly where to stop: Ptolemy, having once formed the idea of a bounding *terra incognita*, extended it round nearly the entire circuit of the known world. All the reports of the circumnavigation of Africa were rejected; that continent was represented as stretching indefinitely south, and it was even carried round to join the east of Asia, and form the Erythrean or Indian sea into a vast basin. Thus the whole system and structure of these two continents underwent, in the hands of Ptolemy, a complete transmutation.

SUBJECT. 1. *Europe.* (Fig. 10.)

138. *In regard to all the remoter boundaries of Europe*, Ptolemy displays an advancement in knowledge, which M. Gosselin considers as truly wonderful, considering the short period which had elapsed since the days of Strabo. The facts which we have stated under the head of Roman geography show the vast additional mass of information derived from the conquests of Cæsar, and from the imperial surveys. This having been incorporated into the writings of Mela and Pliny, a century before the age of Ptolemy, would easily, through these and other channels, reach his knowledge. It is not surprising that the crude delineation of the exterior coasts of Europe under the Strabonic system should have been materially amended; that Spain should have now a southern, and Gaul a western coast; and that the Bay of Biscay should appear clearly under the appellations of the Cantabrian Ocean and the Aquitanian Sea. In regard to Britain, also, or, at least, England, a great reform had been effected. Its coast, after passing the promontory of Kent, bends inward toward the estuary

of the Thames, called here Idumanus. Still more decided, on the opposite side, is the "*Sabrina estuarium*" (the estuary of the Severn), a very appropriate appellation for the Bristol Channel. The projection of Wales, and its entire outline, appears then drawn in a very unexceptionable manner. With regard to Ireland, Ptolemy has not been able wholly to shake off the erroneous impressions of the first Alexandrian school, according to which that country lay to the north of Britain. He makes it west, indeed, but at the same time greatly too far north, its southern coast being on a line with that of Lancashire, or, at least, with the north-western point of Wales. The consequence is, that the island of Mona (Man) is placed off the south-eastern point of Ireland, not far from Wexford. Having pointed out this great error, we must add, that the whole form and circuit of Ireland is given with a correctness which appears very surprising, when contrasted with so great a mistake as to its relative position. Again, the eastern coast of England proceeds correctly till it reaches the vicinity of York, when an aberration takes place of the most extraordinary nature. The rest of the English coast, with the whole of that of Scotland, instead of ranging from north to south, runs from west to east. The eastern coast becomes thus the southern, the western becomes the northern; and the coast of Germany appears opposite and parallel throughout its whole extent. The most northerly extremity of Britain is thus fixed at a point which Mr. Pinkerton supposed to be the Mull of Galloway, but which seems more probably to be some point near Port Patrick, which might be supposed the most westerly, for the west is here the north. It is part of this arrangement, that the *Æbudæ* (Hebrides) are placed in the Deucalionian Ocean, which washes the western coast of Scotland, made here the northern; and the Orkneys are in the same ocean; for, instead of following the line of the main land, they are placed, as, indeed, they ought to be, north, becoming thus at right angles to that line.

138. *To account for this strangely distorted form of northern Britain*, M. Gosselin has, formed a very ingenious theory. The southern extremity of the island being in lat. 52° N., and Thule, the remotest extremity, in 63° , Ptolemy could not, within these limits, find space for that vast expanse of coast, which the itineraries represented to him as belonging to Britain. To make out this space he had no alternative but to give to the northern part the form it actually bears in his maps, and under which the latitude is augmented only by the breadth of Scotland, a much smaller dimension than the length. The question, however, is, by what circumstance Ptolemy was checked in his latitude of Thule, and why he should not have driven it out to the north as far as his itineraries seemed to require. We at one time thought it possible that this grand boundary point might have been fixed by some rude observation which was not applied to the intermediate points. But it appears very improbable, that any expedition which should have made an observation of latitude at Shetland, should not have done the same in the southern and much more accessible parts of Britain. I rather incline to adopt the following solution. We have seen, that, in the ideas of the Roman navigators, Thule was in a great measure separated from Britain, and attached to the east of Germany, or rather to Scandinavia; whether its existence was made known to them by Scandinavian navigators, or whether a part of the coast of Norway was actually fixed upon by them instead of Shetland for this most northern limit of the earth. This idea, which attached Thule to Scandinavia, appears to have been combined in Ptolemy's mind with that of Pytheas, who made it the remotest extremity of Britain. Such a combination could be accomplished only by stretching Scotland across the German ocean in that strange direction.

140. *The details of Scotland*, if we pass over this radical error, are given in a manner much more tolerable than could have been expected in a country unsubdued by the Romans, and with their imperfect navigation. Thule, in Ptolemy, is not a cluster of islands, like those of Shetland, but one large island, upwards of a hundred miles in length: this circumstance more and more strengthens the suspicion that Norway, to a considerable extent, entered into the idea attached to that celebrated name.

141. *Under the heads of great Germany and of Sarmatia*, Ptolemy has given all the knowledge he had acquired of the north and east of Europe, which was not inconsiderable. The line of the German coast is very well formed, and the Amasius or Ems, the Visurgis or Weser, the Albis or Elbe, the Vedra or Oder, and the Visula or Vistula, appear in regular succession, and almost under their modern names. Jutland appears as the Cimbric Chersonese, and the southern coast of the Baltic is carried on very correctly; but, in regard to Scandinavia, he fails entirely. Evidently ignorant that the Baltic is an enclosed gulf, he calls it "the Sarmatic Ocean," and places in it four islands. Three of these, close to the Cimbric Chersonese, are clearly recognised in the islands of Denmark; but the other, of greater extent, farther to the east and opposite to the mouth of the Vistula, is probably part of Sweden, and perhaps Gothland. It is clear, that navigators had not then rounded Jutland, and passed through the Skagerrack or Cattegat, otherwise they must have noticed these straits, and the great extent of continent opposite the Cimbric Chersonese. The Aloecian islands, however, situated off the northern extremity of Jutland, must have been suggested by some part of the Norwegian coast, as there are no islands in that quarter. The more northern part of the Norwegian coast was probably, as already observed, identified with Thule.

142. *The coast of Sarmatia* is described by Ptolemy on passing the Vistula, and he traces with accuracy the great bend which it takes northward to the gulf of Riga. Four rivers are given, which cannot be recognised by their names, but which M. Gosselin conceives to be the Pregel, the Niemen, the Windau, and the Dwina. Beyond this he places "the end of the sea of the known land," and immediately commences that boundary of *terra incognita* which he carries around the whole of Asia.

143. *In regard to the south of European Russia*, Ptolemy recovers much of the knowledge which had been wholly or partially lost under Strabo. He appears indeed to have gone back in a great measure to Herodotus, whom he imitates in giving most unreasonable extension to the Palus Mæotis. There is little room for complaint as to the Tanais, the Borysthenes, and the other great rivers which fall into the Euxine. In this remote and

wild extremity of Europe, however, he has found a place for certain poetical and historical fictions, which experience had banished from better known quarters, but which could not find a place here with any propriety; — the grove of Diana, the race-course of Achilles, the altars of Cæsar and of Alexander; neither of whom ever carried their arms into this part of the ancient Scythia.

144. *In tracing the Mediterranean*, Ptolemy improves considerably upon the labours of his predecessors. Sicily, in particular, is much better constructed, and the straits of Messina are placed nearly in their true latitude. He still, however, merits deep reproach for the utterly barbarous form, as M. Gosselin justly terms it, which he has given to Italy, that ruling country, which must of all others have appeared to him the most interesting, and for which he must have possessed the most ample materials. Yet Italy, with the exception of a slight bend at its extremity, is oriented almost entirely east and west, having the Adriatic for its northern, and the Tyrrhenian for its southern boundary. I cannot find any account of an error so strange, except by supposing that Ptolemy must have been led into it by one of those itinerary maps which, like the Peutingerian, made every thing subservient to the direction of the Roman high road, and drew it in a straight line from one extremity to the other. It is easy to suppose that he might not comprehend the very odd principle upon which this map was constructed, and might conceive that being made with regard to Italy, a country so near, and so completely within reach, it might be implicitly relied on. This suspicion is strengthened when we find, after passing Dyrrachium, the port of embarkation for Greece, this being the direction of the great road of the empire, that the coast of Italy suddenly resumes its just form, and the peninsula of Campania makes even too abrupt a bend to the south.

SUBSECT. 2. *Asia.*

145. *In regard of Asia also*, important discoveries had been made since the time of Eratosthenes. Immense territories, included by that geographer within the domain of the ocean, were known to Ptolemy as occupied by the wandering hordes of Scythia, or by the peaceful and industrious nation of the Seres or Chinese. This advantage might be partly due to the military itineraries, especially that of Trajan in his victorious expedition into Parthia. The grand source, however, evidently was that bold spirit of commercial enterprise, to which an impulse was given by the vast consumption of Rome, when the wealth of the world centred in that mighty and voluptuous capital. The East was the region mainly resorted to for the supply of the boundless wants which arose in that artificial and luxurious state of society. The merchants soon learned to trace routes, both by land and sea, much longer and more adventurous than had been achieved by their predecessors at any former period. Under the narrative entitled “the Periplus of the Erythrean sea,” we have followed the maritime career by which the merchants of Alexandria were led to the coast of Malabar. Whether, in the time of Ptolemy, the Greek navigators had actually proceeded farther, it may be difficult to say with certainty. He has certainly, however, obtained a considerable accession of knowledge with regard to this eastern extremity of the known world. He goes far beyond the mouth of the Ganges, at which we have observed the termination of all precise knowledge in the author of the Periplus. After delineating a coast, with a succession of ports which it is difficult to identify, he comes to a grand feature, which he calls “the Golden Chersonese,” formed by three great estuaries discharging their waters into the sea. These phenomena are actually presented by the mouths of the Irrawaddy at the southern extremity of Pegu. This is followed by an extensive feature, the *Magnus Sinus*, or Great Bay, penetrating far inland, and receiving some considerable rivers. The gulf of Malacca is not nearly so large or so deep as this *Magnus Sinus*; but its mouth being very broad, and its shores very winding, it is not very improbable that, in the eyes of ancient and unskilful navigators, it might assume this exaggerated form and dimension. Beyond the *Magnus Sinus* the coast, in continuity with its eastern shore, stretches due south to the farthest known extremity of the world. On this coast the leading features are Thina, a great interior metropolis, and Cattigara, its sea-port at the mouth of the river Cotiaris. This coast, it should seem, can only be that of Malacca and the Isthmus of Kraw, which runs exactly in the direction here assigned by Ptolemy. Gosselin identifies Thina with Tenasserin; but there seems more reason for acceding to Dr. Vincent’s opinion that it is Siam. This exposition, which is supported by Vossius, Gosselin, and Vincent, appears to me undoubtedly preferable to the more general one supported by the authority of d’Anville, which makes the coast of the Sinæ extend along the gulf of Siam and the sea of China. Such a line would involve Ptolemy in the strange and incredible blunder of making a coast face the east which really faces the west. Sumatra, indeed, is so land-locked that it might easily enough have been taken for a part of the continent, and have been called the Golden Chersonese. But it seems inconceivable how the straits of Malacca and of Sunda, so important and so critical to navigators, and by one or the other of which they must have entered the sea of China, could have been overlooked. On this supposition, indeed, the coasts are swelled very far beyond their due dimensions; but we have often remarked how enormously this is apt to be the case, in regard to routes, and above all coasts which are traversed for the first time, and by inexperienced navigators. Ptolemy, as we have seen, after retrenching the eastern itineraries of Marinus one half, left them still greatly too large; and he does not mention any similar retrenchment in regard to the coasts. If, on the other hand, those of Ptolemy extend to the Chinese sea and to China, then, contrary to every ancient example, he must have immensely underrated the extent of these imperfectly discovered tracts; an error which would be contrary to all precedent: — this, however, does not imply that there may not, within this line of positive knowledge, have been a confused blending of features that lay in reality beyond.

146. *The increased knowledge of Ptolemy respecting the eastern part of the Asiatic continent* was chiefly derived, as we have already remarked, from the great caravan which proceeded from Byzantium, having the country of Serica for its ultimate destination. This caravan, having traversed Asia Minor, crossed the Euphrates at Hierapolis, and journeyed through Media, by way of Ecbatana (Hamadan), to Hecatompylos (Daumghaun), the capital of Parthia. It then advanced north to Hyrcania (Horkan or Jorjan), thence south, to take in the fine province of Aria (Herat). It now again turned north, to include the capital of Margiana (Meru Rood), thence due east to Bactria (Balk), which then formed, as at present, the main centre of the commerce of interior Asia. The caravan now quitted the easy and level tract through which its route had hitherto led, and began to ascend that vast and rugged mountain world which fills the eastern interior of Asia. After accomplishing the steep ascent of the *Montes Comedorum*, which seems to be the chain of the Beloor, it reached a station called the "Stone Tower," which there is nothing to identify, except that the direction towards it is north-east, and it may be either Ladauk or Yarcund, the great modern emporium of this part of the East. From the Stone Tower to the frontier of Serica, Marinus, on the authority of the merchants, reported a journey of seven months, which Ptolemy considers as monstrous and incredible, though he admits that the road is exposed to the greatest hardships and difficulties. The question, what is the country described by Ptolemy and his contemporaries as Serica, is the most curious in the ancient geography of Asia. The earliest modern opinion identified Serica with northern China, while the country of the Sinæ composed the southern part. D'Anville, however, who transported the Sinæ into the coast of Cambodia, carried westward also the Seres into the country of the Igours, or Eygurs, including in their territory only the small projecting portion of the Chinese province of Shensee. Mr. Pinkerton places it still farther west, in Little Bucharía. M. Gosselin, followed generally by the present French school, contends that Serinagur, in the north of Hindostan, is the real Sera metropolis of Ptolemy. I can see no reason for altering the grounds on which I concluded formerly, and endeavoured to prove, Serica to be simply China. (See *Edinburgh Phil. Trans.* vol. viii. On the Ancient Geography of Central and Eastern Asia.) All the natives of India whom Ptolemy saw assured him that the Seres lay beyond the Sinæ, and China is beyond Siam. The Sinæ (Siam) had to the south Scythia beyond Imaus, which country had Serica on the east. Serica is described as traversed by two great rivers, flowing westward, as the Hoang-ho and Yang-tse-kiang actually do. Serica, according to Ptolemy's graduation, was fourteen hundred miles from north to south, and eleven hundred from east to west, a very close approach to the dimensions of modern China. Serica, then, in form, extent, geographical features, and relations to the neighbouring countries, exactly corresponds to the modern China. Not less conformable is the report given of the national character. The Seres are represented as frugal, quiet, sedate, and tranquil beyond all other nations; as of all others the most unwarlike, and the most averse to the use of arms; as shunning, with the most studious care, the society and intercourse of strangers, and scarcely ever allowing them to enter their territory; as carrying on trade at a fixed frontier station only, and under the strictest precautions; as selling their own commodities without receiving the commodities of other nations in return. Silk was the staple of Serica, and it is of China. With regard to M. Gosselin's Indian theory, it must now, we suppose, be on all hands given up, since Thibet and Northern India, instead of being connected by the valley of the Ganges, have been found separated by the unbroken continuity of the loftiest ridge of the Himalleh, which can be penetrated only by a few most perilous and tremendous passes.

147. *Respecting Indostan, and its liminary regions*, the details given by Ptolemy include a great mass of sound information. In some important particulars, indeed, his map is decidedly superior to those possessed by the moderns, previous to the late important accessions to their knowledge. He describes the Ganges rising, as it really does, on the southern side of the Himmaleh, and in the outer limits of Indostan, while, prior to the mission sent by Col. Colebrooke, in 1808, its origin, and a considerable part of its early course, were supposed to be in Little Thibet. The mission to Caubul first found that all the great western rivers emptied themselves by one channel into the Indus, as they had been represented by Ptolemy, while modern maps had exhibited them entering by two great separate channels. The same mission discovered two very considerable rivers, western tributaries of the Indus, the Kaumeh and the Suaat, of which no trace had yet appeared in modern delineation; but, on turning to Ptolemy, we find them accurately traced under the names of the Coe and the Suaste. Thus we find him delineating with success geographical features in the most secret recesses of Asia, which remained unknown till lately to the best-informed of modern geographers.

148. *The site of Palibothra* is one main point in which, after much discussion, geographers have in vain endeavoured to form an unanimous opinion. It was found by Megasthenes the proud capital of the Gangetic kingdom, and the greatest city of all India. Yet modern geographers have not been able to agree within several hundred miles upon this marked and celebrated position. Arrian states that it is situated at the junction of the Ganges with the Erranaboas, the third river of India as to magnitude, being surpassed only by the Ganges and the Indus. This scale of magnitude suggests the Jumna, and at the confluence of the Jumna

with the Ganges actually stands Allahabad, a city of great magnitude and high antiquity, which is even revered by the Hindoos as the "king of holy cities." Upon this general idea d'Anville and, after him, Robertson, have considered Allahabad as occupying the site of Palibothra. On examination, however, this is found in contradiction to the most positive statements of Pliny and Ptolemy. Pliny, in express words, states Palibothra to be 425 miles distant from the junction of these two rivers. Ptolemy makes the distance somewhat greater still. In considering Allahabad, then, as Palibothra, we abandon altogether the authority of these two great geographers, a step in which we should be very little justified, either by a reference to their general character, or by our knowledge of their remarkable accuracy with regard to the other features of central and northern India. Their account of Palibothra, too, is given upon the authority of Greek ambassadors, who actually visited that capital. The river next in magnitude is the Gogra or Sarayu. But the junction of this river with the Ganges is not nearly so far from that of the Jumna as the above statements would require. Besides, Ptolemy actually gives us the Sarabus (Sarayu), with its junction in the due relative position to that of the Jumna, but Palibothra much farther down. Major Rennell has made choice of Patna, and considers the junction of the Soane, at present thirty miles above that city, as having taken place formerly by a different and nearer channel. This theory stands on much higher ground than the other; yet it by no means closely corresponds with the ancient data. Pliny mentions both the Sonus and the Erranaboas as quite distinct tributaries of the Ganges, and he places the city considerably farther down than Patna is. Ptolemy also, in giving the junction of the Soa and the Ganges, places Palibothra more than two hundred miles below. Major Rennell's theory, then, brings us considerably short of the point at which this great capital ought to be situated.

149. Another point which appeared to me to unite the name and position of Palibothra has been mentioned (*Discoveries in Asia*, v. i. p. 491.), and, without being inclined very confidently to dogmatise, it still appears to me to combine better the different requisites than any other yet named. The name of *Boglipoor* may be considered identical with Paliboor; for, in transferring Indian terms into our characters, P and B, O and A, are always used promiscuously; and the termination attached by the Romans is evidently according to their system of harmonising foreign sounds with their own. A name is of little consequence when it is not accompanied with a corresponding position; but here this appears to coincide nearly, though not indeed quite exactly, with Pliny. He makes Palibothra 430 miles from the junction of the Ganges and Jumna, and 600 from Gange, a capital situated at the mouth of the former. Boglipoor, however, instead of being only two-fifths of the distance between these two points, is about exactly midway. The space lower down the river, being less known, might more readily have been exaggerated, and Gange being on the most easterly branch of the Ganges, might occupy nearly the position of Islamabad. The place assigned by Ptolemy is exactly midway, and therefore coincides strictly with the position of Boglipoor. Near it the Ganges receives the Coosy, or river of Nepaul, certainly not the third in India as to magnitude; but the ambassadors might not have very precise means of ascertaining the relative dimensions of the Indian rivers. There is, therefore, a great weight of evidence, as to name and position, in favour of the theory here proposed. I must confess, however, that I find no description of any monuments, such as might be expected to mark the ancient site of so splendid a capital. Indian structures, however, are not usually composed of materials sufficiently solid to resist the ravages of sixteen centuries. If the local data could at all have allowed us to fix upon the thrice ancient and holy Benares, its character would have given it at once a pre-eminence; but this is impossible. Rajemahl, suggested, is not very distant from Boglipoor; but besides losing the coincidence of name, it agrees less than the other position with the statements both of Ptolemy and Pliny.

SUBJECT. 3. *Africa.*

150. In the delineation of Africa, Ptolemy, himself an African, had obvious advantages. Accordingly his delineations of several of the most interior features have, as in the case of southern India, proved to be more accurate than those given by modern geographers down to a very recent period. The course of the Nile, up to its highest probable source in the central range of the mountains of the Moon, has been justified by recent enquiry, in opposition to the Portuguese missionaries, who drew it from the mountains and lakes of Abyssinia. This original fountain-head has not yet been traced by the daring foot of the modern traveller; but the description given to Brown, of its descent from the great mountain chain south of Darfoor, corresponds very exactly with Ptolemy, making allowance only for his erroneous graduation. With equal fidelity, he delineates the Astabóras, or Atbara, the As-tapus, or river of Abyssinia, successively falling into it from the east. He has, indeed, made Meroe an island, enclosed by branches of the Nile; but modern discovery has shown it to be so very nearly insular, in consequence of the great bend taken to the south, that the error cannot be considered excessive.

151. In regard to central Africa, Ptolemy had not equal advantages, on account of the distance, because no track had yet been formed across the vast ocean of desert which intervened. It appears to me a matter of some difficulty to ascertain the precise extent of his knowledge as to this region. M. Gosselin has not hesitated to assert, that he knew nothing of Africa south of the desert, and that all the features which he has assigned to interior Libya, and the course of the Niger, belong in fact to Fezzan and that region behind the Atlas which we call the B'led-el-Jereede, or Land of Dates. This opinion certainly receives much countenance when we find the Garamantes and the Garamantica vallis placed on the same line with the Niger, the lake of Nigritia, and the other leading central features. I still, however, think it probable that Ptolemy might, by way of the Upper Nile, have obtained intelligence respecting a portion at least of these vast regions, the approach to which by way of Dongola and Sennaar was not obstructed by any very insurmountable barriers. Besides the agreement of several names, as Gana, Tagana, Panagra, the general picture of this region as one of lakes, rivers, and mountains, agrees much better with the interior than with the arid tract between Atlas and the desert. My suspicion therefore is, that Ptolemy, unacquainted with any route across the great desert, was not aware of the wide interval between the features to the north and those to the south of it, and linked them together in his description as contiguous and connected. As his knowledge of central Africa was thus obtained only in a westerly course from the Nile, it was not likely to extend beyond the eastern part of the vast breadth between the Nile and the ocean. The Mons Mandrus, his most western feature, with a great river flowing from it into the lake of Nigritia, may perhaps be recognised in the mighty range of the mountains of Mandara and the river Shary flowing from them into the lake or sea of the Tchad. About this quarter I should conceive the knowledge which reached Ptolemy by inland channels probably terminated; and the Atlantic coast, known to exist by the voyages of Hanno, Scylax, and Polybius, was united to these objects by a merely hypothetical construction. In regard to the course of the Niger, it is difficult to say very precisely what were Ptolemy's views, and we only perceive that he made it an inland river, neither flowing into the Atlantic, nor by the Nile into the Mediterranean.

152. Respecting this great central region of Africa, however, Ptolemy had obtained some notices from which he might have estimated its magnitude. Two Roman expeditions had been reported to him, one made by Septimius Flaccus from Garama, and the other by Julius Maternus from the coast of Cyrene. The former in three, and the latter in four months, had penetrated into the country of the Ethiopians. Ptolemy expresses himself very sceptical as to the possible length of this march; nevertheless he lays down the country of

Agisymba as that farthest region of interior Ethiopia into which these commanders had penetrated. Agisymba we suspect to be Agadez; at least as the march comprehends no rivers or lakes, it cannot well have reached the line of the Niger. Nevertheless Ptolemy places it considerably to the south of Nigritia; which is doubtless in favour of the limited extent which M. Gosselin allows to his information. But we may observe that, supposing Ptolemy to have formed, in the manner above supposed, his idea of the plain of the Niger as little removed to the south of Fezzan, he must, in protracting marches of three or four months, necessarily have carried the line much farther to the south.

153. *In regard to the western coasts of Africa*, Ptolemy's delineation is not very luminous, but appears on the whole to favour M. Gosselin's views respecting the extent of Hanno's voyage and of the knowledge of the ancients. He does indeed present two rivers, the Daradus and the Stachir, flowing on a line with the plain of Nigritia. But I have no idea that Ptolemy could have any precise information reaching across the entire breadth of the continent, and conceive, as already hinted, that the coast and the interior were here hypothetically united. As Ptolemy placed the plain of the Niger much too far north, he might make these rivers on a line with it, without identifying them with the Senegal and Gambia. His position of the Fortunate Islands (Canaries) opposite to their mouths, and south of Cerne, is not at all in favour of the opinion which carries these last features deep into central Africa.

154. *On the eastern coast of Africa*, Ptolemy adds to the line described by the author of the Periplus a coast extending from the promontory of Rhaptum to that of Prasum. At this point the coast, hitherto running south-west, changes to south-east. No details are given of this coast, which is described as rough and difficult to navigate. We can neither, with M. Gosselin, limit Prasum to Brava, nor with Vincent carry it so far as Mosambique. There is no part of the coast to which the direction assigned to it belongs, except from Quiloa to Cape Delgado; and if Rhaptum be at or near Quiloa, the latter, allowing for some exaggeration of distance on a coast so little known, will be the promontory Prasum. Five degrees east and three degrees south of this promontory is the island of Menuthias. The Menouthesias of the Periplus appeared pretty plainly to be one of the smaller islands near the African coast, and probably Zanzibar; but none of these could be the Menuthias of Ptolemy, which is manifestly Madagascar.

BOOK II.

GEOGRAPHY OF THE MIDDLE AGES.

155. *Under the "geography of the middle ages"* may be comprehended that of the Arabian or Saracen nations, during the period when science was successfully cultivated among them; and the geographical ideas prevalent in Europe, during that long darkness which preceded the revival of learning, and the commencement of maritime discovery.

CHAP. I.

ARABIAN GEOGRAPHY.

156. *The Arabs* were for some time the most learned of nations. As the mantle of science dropped from the sages of Greece and Rome, it fell upon this wild and strange race, sprung from the bosom of bigotry and barbarism. The fanatic hordes, who, under the guidance of their false prophet, rushed from the heart of Arabia, at first owned no law but the Koran and the sword. When they had conquered half the world, however, and founded splendid capitals on the banks of the Euphrates and the Guadalquivir, there arose a race of humane and polished princes, who studiously sought to relumine the almost extinguished lamp of science. Almamoun above all, in the ninth century, may rank among the most distinguished of its patrons who have ever filled a throne.

157. *Geography, among the Arabian states*, appears to have been studied with greater ardour than at any other place or country, except at Alexandria. It employed the pens of several of their most eminent writers; Masudi and Ebn Haukal in the ninth and tenth centuries; Abulfeda and Edrisi in the twelfth and thirteenth; to whom may be added the respectable names of Ibn-al-Vardi, Bakoui, and Scheabeddin. Although none of their works have become at all familiar to the European reader, yet learned men have translated portions, which not only convey a general idea of their system, but have enabled geographers to delineate some districts of the globe which otherwise would have long remained unknown.

SECT. I. General System. Fig. 11.

158. *The mathematical sciences, and above all astronomy*, were among the most favourite pursuits of the court of Bagdad; and the ample resources which they afforded were applied with considerable care to the improvement of geography. In 833, the caliph Almamom endeavoured, by observations of latitude made at Kufa, and at a point in the desert of Palmyra, to measure the circumference of the globe. In all the countries subject to the Mahomedan arms, numerous observations are recorded which, though not always rigorously correct, appear at least to have been real, and not merely calculated out of itineraries, like those of the Alexandrian geographers. The tables of Abulfeda, of Ulug Beg, and of Nazir Eddin,

edited by Graevius, and republished by Hudson, afford materials that are still useful for the construction of the maps of interior Asia.

159. Many countries, hitherto unknown and barbarous, were explored, and in some degree civilised, by the Moslem arms. Those on the Oxus and the Jaxartes, the Asiatic Scythia of the ancients, and occupied then only by Nomadic hordes, were covered by them with great and flourishing cities. Among these, Samarcand became afterwards the capital of an empire that extended over half of Asia. At the opposite extremity, Mauritania, which had been regarded by the Romans as almost beyond the limits of social existence, became a flourishing kingdom, and possessed in Fez an eminent school of learning. Even beyond the limits of the Mahomedan world, missions were sent to explore the remotest limits of the east and

west. One interesting result of these has been communicated in the relation of two Mahomedan travellers, Wahad and Abuzaid, who in the ninth century penetrated into China; and gave a description of that country; which, though only recently known to us by the translation of Renaudot, must have been the earliest ever communicated to the nations of the west. From Lisbon, also, the brothers Almagrurim sailed, endeavouring to anticipate the discoveries of Columbus, by exploring unknown countries beyond "the sea of darkness." For ten or eleven days they steered westward; but seeing a storm approaching, the light faint, and the sea tempestuous, they dreaded having come to the dark boundaries of the earth. They turned therefore south, sailed twelve days in that direction, and came to an island, which they called Ganam, or the island of birds; but the flesh of these birds was too bitter to be eaten. They sailed on twelve days farther, and came to another island, the king of which assured them that their pursuit was vain: that his father had sent an expedition for the same purpose; but that, after a month's sail, the light had wholly failed, and they had been obliged to return. The adventurers, therefore, made their way back to the coast of Africa, which they reached in three days. The bearings stated seem to point out Madeira and the Canaries as the two islands visited in this expedition.

160. *In regard to the general outline of the earth*, the Arabs seem to have closely adhered to ancient theories. They revived the early impression of an ocean, which, like a zone, encompassed the whole earth. This, according to a natural feeling, was characterised as the "Sea of Darkness," an appellation most usually given to the Atlantic; but the northern sea of Europe and Asia, inspiring still more mysterious and gloomy ideas, is called the "Sea of pitchy Darkness." Edrisi has even imaged the land as floating in the sea, and only part appearing above, like an egg in a basin of water. At the same time he divides it into seven seas, fancifully appropriated to the seven climates into which the earth was divided. According to these climates, he describes the earth beginning at the western and proceeding to the eastern extremity; an ill-judged arrangement, which, by a mechanical section, separates portions of territory the most intimately connected. The knowledge of the Arabs was subjected to another and a voluntary limitation. They studiously desisted from all enquiry respecting those blinded nations, whose minds had never been illumined by the light of the Koran. Ibn Haukal even makes it a subject of glory, that he had found nothing worthy of remark among nations who could not be viewed without horror by men who had any innate principles of virtue, wisdom, or religion. These views of the subject greatly restricted their means of knowledge in respect to Europe, and rendered it of little value, unless with regard to those two continents, which their arms had rendered to a great extent Mahomedan.

SECT. II. *Asia.*

161. *The Asia of the Arabs* comprised a wider range than had belonged to that continent under any former system. China is distinctly marked, partly under the appellation of Seen, and partly under that of Cathay; the former term appearing to comprehend India beyond the Ganges. Lamery, productive in camphor, gold, ivory, and dying-woods, appears by these products to be Sumatra, and mention is even made of Al Djavah. The countries on the Oxus and Jaxartes having become the seat of an extended Moslem empire, of which Samarcand was the capital, Tartary both eastern and western was, for the first time, delineated with tolerable accuracy; many of the leading positions, in this hitherto inaccessible part of the continent, were even fixed by astronomical observation; and some positive though faint and indistinct notice appears to have been received respecting the people situated along the shores of the Northern Ocean. Unfortunately the main objects of curiosity and enquiry were Gog and Magog. The authentic application of these names has been observed under the Hebrew system as belonging to a devastating race from the shores of the Euxine and Caspian. Oriental fancy had transformed them into two enormous giants, who had erected an impregnable castle on the borders of Scythia. The efforts made by the court of Bagdad in pursuit of this chimera were very extraordinary. The first expedition was undertaken with the hope of finding it somewhere on the shores of the Caspian; but as their conquests soon embraced the whole of that region, without the slightest trace of this tremendous castle, the more southern country of Bokhara was the next object of search. When that also had been surveyed in vain, the court was involved in much perplexity, and scarcely knew to what ulterior region their view was to be directed. At length one of the caliphs despatched a mission, with strict injunctions on no account to return without having discovered the castle of Gog. The envoys, according to Edrisi's report, proceeded first along the shores of the Caspian, then through a vast extent of desert, probably the country of the Kirghises, when they arrived at a stupendous range of mountains, which must have been the Altai. Here they did actually find or pretend to find something which they concluded to be the castle of Gog and Magog. Perhaps they reached some of those ancient monuments which have been found along this range, and gladly embraced this pretext to rid themselves of so troublesome a commission. The picture they drew of it was certainly very highly coloured, according to Oriental taste. The walls were of iron cemented with brass, and a gate fifty cubits high was secured by bolts and bars of enormous magnitude. The minds of the Arabs were thus set at

rest, and in all the future delineations of Asia this mighty castle was seen towering at its farthest extremity.

SECT. III. *Africa.*

162. *In regard to Africa, the wide-extended settlements of the Arabs* afforded them new sources of information. The Mediterranean coast, indeed, as far as Numidia, had been fully explored by the ancients, and had even formed a more intimate part of their political system than it has done of that of the moderns. By the Arabs, however, who had established here a succession of kingdoms, it was described in greater detail than ever; and as the most western of these kingdoms was the flourishing one of Morocco, this region, comprising the nearly unknown tracts of ancient Mauritania, formed an almost entirely new acquisition to knowledge. But their grandest achievement consisted in forming a road across the Great Desert, and in colonising a considerable part of the central regions of Africa. They here founded a series of powerful kingdoms: Ghana, the modern Kano; Tocrur, which we conceive to be Sackatoo; Kuku and Kauga, which recent travellers have found in and near the modern region called Bornon. They described those countries as situated on the Nile of the Negroes, which, contrary to ancient opinions, they represented as rising indeed from the same fountain with the Nile; but as flowing westward across all Africa, and falling into the Atlantic ocean or sea of darkness. At its mouth they placed the island of Ulil, whence salt was conveyed to all the Negro territories, which were entirely destitute of that necessary of life. This view of the subject, though erroneous, was naturally suggested by the course of the rivers within the region with which they were alone intimately acquainted; but we reserve this discussion for a separate chapter, when we propose to give a succinct view of the successive theories respecting this great African river. We shall at present only observe, that, as Tocrur is described to be only eighteen days' journey from the ocean, it is plain that the knowledge of the Arabs did not extend to Tombuctoo; that they knew nothing of the Senegal or Gambia, or the countries upon these rivers; and that the ocean into which they represented the Nile of the Negroes as falling was either a hypothetical feature altogether, or was at least hypothetically connected with all that they knew of the eastern tracts of interior Africa.

CHAP. II.

EUROPEAN GEOGRAPHY DURING THE DARK AGES.

163. *Even the imperfect knowledge possessed by the ancient geographers* became involved in the general progress of that intellectual darkness, which ensued on the decline of the Roman empire. Europe, overwhelmed with a deluge of barbarism, no longer cultivated art or science; and the rude states into which it was divided had only a vague idea of each other's situation. The advance of this darkness may be observed in an anonymous work, published at Ravenna in the eighth century. The writer presents only confused fragments of the information contained in Ptolemy and Pliny. The coast of India, indeed, the mercantile route to which appears to have been kept open, is still delineated with some degree of correctness. But the whole interior of Asia, from China to Bactriana, is included under the name of "Seric India:" the Caspian re-appears as a gulf of the Northern Ocean; in short, all these distant regions are viewed, in the manner natural to ignorance, as a dim and indefinite expanse, the features of which were all confusedly blended with each other.

164. *The monasteries during the dark ages* afforded an asylum for all that remained of ancient knowledge; in them the manuscripts of many of the classic writers were still preserved, though little consulted. The reading aloud of histories, and descriptions of neighbouring, and even of distant countries, formed a mode of beguiling the tedious hours; but these being recorded under the title of "Wonders of the World," and crowded with the most extravagant fables, served rather for the amusement of the fire-side, than for any real instruction.

165. *The missions undertaken for the conversion of the northern pagans* were the principal channel by which any geographical knowledge was conveyed. The missionaries did not, at this time, attempt to pass the limits of Europe; but directed their efforts towards the conversion of the Slavonic tribes, who occupied Poland, Prussia and Livonia. *Otho* appears even to have penetrated through the interior of Russia to the White Sea; he undertook also an extensive voyage along the coasts of Norway. The Anglo-Saxon Wilfrid, named by the pope the apostle of the Germans, appears to have been the person who transmitted the most full details relative to the Slavonic tribes. St. Otto, bishop of Bamberg, and Anscuire, a monk of Corbie, penetrated to the kingdoms of Sweden and Denmark; but the details of their mission have not been preserved. Although, however, the monks thus did something to illustrate the geography of Europe, there is sufficient evidence that they laboured,

in many instances, under the grossest ignorance ; some of them knew not even the capital of their own country, or the cities nearest to their own.

166. *The great monarchs* made some efforts to rescue the age from this state of profound ignorance. The two illustrious monarchs, Charlemagne and Alfred, distinguished themselves by their endeavours to promote geography : the former constructed a silver table of large dimensions, on which was delineated the whole world so far as known to him ; unfortunately the materials were too costly, and the silver world was soon melted down to supply the necessities of one of its kingdoms. Alfred produced a more valuable monument in a description of the north of Europe, from the best materials which could be then collected, and which forms still the best record of the geographical knowledge of that age. Under the direction of William the Conqueror was drawn up that important document called Domesday Book, in which the population, the culture, and the taxes paid by each district, are exhibited in the greatest detail. A similar survey of Denmark was made in the thirteenth century, by its sovereign Waldemar II.; and of the Mark of Brandenburg, in the fourteenth century, by the emperor Charles IV.

167. *The Danes and Norwegians, the Northmen* as they were called, while under their mighty sea-kings they spread desolation over the maritime districts of Europe, necessarily acquired a very extensive knowledge of its seas and coasts. Such knowledge, though nowhere formed into any regular system, may be traced in the sagas, or metrical histories, in which they celebrate the gallant exploits of their countrymen. They were, of course, familiar with all the countries bordering on the Baltic. They knew by conquest Orkney, Shetland, the Hebrides, and the western coast of Ireland. Their fleets reached even the shores of Italy and Sicily. Towards the north, they established colonies in Iceland and Greenland. But the most important discovery of the Northmen was, undoubtedly, America, if their claim to the merit of that discovery shall be admitted to be made good. In the beginning of the eleventh century, Thorwald and Leif, two natives of Iceland, having sailed far to the southwest, came to a country which appeared to them, doubtless by comparison, to be mild and agreeable ; the natives were of dwarfish stature, and maintained with them sometimes a hostile, but oftener a friendly intercourse. Finding that the rivers abounded with fish, and that the finest furs could be procured, they and their countrymen repeated their visits ; and, in 1211, Bishop Eric is said to have repaired thither with the view of converting the natives. The name given to the region is Vinland, from the *vines* growing in it ; a feature which certainly occurs to us as very foreign to this part of the world ; but, in fact, wild vines are found growing in all the most northerly districts of America. After the most careful examination of this subject, I have endeavoured to show in my late work on American discoveries, that America could not have been reached by the Icelandic adventurers, and that Vinland must have been merely a southerly district of Greenland.

CHAP. III.

GEOGRAPHICAL KNOWLEDGE DERIVED FROM THE CRUSADES.

168. *The crusades* formed a series of events which roused the European mind from its local and limited range, and directed its ken into the regions of another continent. The high-wrought enthusiasm which impelled Europe to pour itself, as it were, in one mass on the eastern world, however blind might have been the zeal which inspired it, was, on the whole, highly beneficial : it drove back the tide of Saracen and Turkish conquest, which might have swallowed up the whole West, and involved it in the same gloom of barbarism and superstition that pervaded the East. Above all, the crusades had a powerful influence in dispelling the mental darkness in which the western regions were involved, and in preparing that light of science and intelligence which was so soon to dawn upon them. The attention of Europe was thus directed to these interesting and memorable regions, known hitherto only by the meagre report of some occasional pilgrims. Not only the Holy Land, with the kingdoms of Jerusalem and Edessa, founded by the victorious crusaders, but the extensive domains belonging to the Saracen and Turkish empires, became objects of enquiry ; search was now made in the writings of the ancient geographers, and perhaps some lights were derived even from the Arabian writers. Sanudo compiled a map of the world, annexed to Bongar's "*Gesta Dei per Francos*," (*fig. 12.*) in which the ideas formed out of the crusading expeditions are fully exemplified : Jerusalem is placed in the centre of the world, as the point to which every other object is to be referred ; the earth is made a circle surrounded by the ocean, the shores of which are represented as everywhere nearly equidistant from that spiritual capital, the site of which is, indeed, remarkable for its relation to the three continents, Asia, Europe, and Africa. Persia stands in its proper place ; but India, under the modifications of Greater and Lesser, is confusedly repeated at different points, while

Fig. 12. SANUDO'S MAP OF THE WORLD.

the river Indus is mentioned in the text as the eastern boundary of Asia. To the north, the castle of Gog and Magog, an Arabian feature, crowns a vast range of mountains, within which it is said that the Tartars had been imprisoned by Alexander the Great. The Caspian appears, with the bordering countries of Georgia, Hyrcania, and Albania; but these features stand nearly at the northern boundary of the habitable earth. Africa has a sea to the south, stated, however, to be inaccessible, on account of the intensity of the heat. The European countries stand in their due place, not even excepting Russia and Scandinavia; though some oversights are observable in the manner in which the two are connected together.

CHAP. IV.

TARTAR GEOGRAPHY.

169. The revolutions of the north of Asia next attracted the eyes of Europeans to the distant quarters of the world. The roaming tenants of those boundless wilds, known under the ancient name of Scythia, and the modern one of Tartary, have at various periods conquered and desolated the civilised world of Asia. The offspring of Tartar chiefs sat for many centuries on the thrones of Pekin, of Delhi, of Ispahan, and of Constantinople: but, of the Tartar rulers, none ever raised so terrible a name, or established so wide an empire, as Gengis or Zingis; originally an individual chief of the Monguls, he attained the general sway over that warlike race, and led them as conquerors from empire to empire. His first and most signal

exploit was the conquest of China; having thence crossed the whole breadth of Asia, he died on the shores of the Caspian. His successors pressed on eastward, overran Russia, and penetrated through Poland into Hungary and Silesia; their approach, their rapid movements, and the exaggerated reports of their ravages, struck the nations of Europe with inexpressible terror; this was greatly heightened by the prevailing ignorance of geography, which was such that none knew when they might arrive, or where they might be encountered. The Danes were thus deterred one season even from going to the herring fishery, on the coast of Scotland. The Tartars defeated and killed the Duke of Silesia; but a general muster of the German chivalry being made to oppose them, they retreated into the interior of Poland, and even farther to the east, leaving only a numerous vanguard; but it was suspected that they were only mustering their strength, again to invade Europe, in more dreadful and destructive array.

170. *Embassy*, at this crisis, was deemed the expedient most likely to appease the fury of these dreaded invaders. According to the ideas of the age, the pope appeared the most respectable character, in whose name a mission could be undertaken, and monks the most fitting ambassadors. The choice was injudicious: these envoys, ignorant of the political relations of countries, of the usages of society, and the mode of treating with mankind, obtained no respect in the eyes of the fierce conquerors of Asia. They returned without fulfilling any object of their mission; and if Europe was not again exposed to this barbarous inundation, it owed its safety only to the division of the immense empire of Kaptchak, and the dissensions among its princes. These ambassadors, however, traversed a large portion of the continent, before unknown to Europeans. One mission, indeed, under Ascelin, which met the Monguls on the frontier of Persia, does not communicate any geographical information; but the journey of Carpini, and after him of Rubruquis, (*fig. 13.*) led them through

Fig. 13. MAP OF THE JOURNEY OF RUBRUQUIS.

the north of Russia, along the shores of the Black Sea, and the Caspian, and thence into the very heart of the immense plains of interior Asia, where they found the great Tartar capital of Karakorum, the chief seat of the posterity of Zingis. Here the masters of the world, while embassies and presents were waiting them from all the courts of southern Asia, were living in the rudest Scythian fashion, feeding scantily on horse-flesh and mares' milk, roving about in tents, destitute of arts, and occupied only with war and plunder. The Tartars, however, treated with a proud disdain all other nations, over whom they held themselves as commissioned by heaven to rule, while they paid the most abject submission to their own Khan, revering him as the appointed representative of deity on earth.

171. *Karakorum* was found scarcely entitled to the name of city, being little larger than one of the suburbs of Paris, and its most sumptuous edifices scarcely suitable to a European country town. The situation of this capital of so great an empire has been a subject of some controversy. D'Anville places it at a point to the north of China, near the eastern limit of the great desert of Shamo or Cobi, while Fischer fixes it on the Orchon, one of the rivers which unite in forming the Selingha. I have elsewhere endeavoured to show (*Discoveries in Asia*, I.) that both these positions must be about a thousand miles to the eastward of the real site. It is true that upwards of four months was occupied in passing from the western frontier of Russia to this capital; and the missionaries complain of the grievous rapidity with which they were conveyed. They estimate the daily rate as equal to the distance from Paris to Orleans, or about seventy miles; and this time and route would doubtless be sufficient to carry them to the most eastern extremity of the continent. But whenever they give us the time actually employed in travelling between known points, a rate is found which does not even approach to the above. Two months are spent by Carpini in travelling from the Dnieper to the Volga, and by Rubruquis from the Danube to the Don, "riding post as the Tartars do;" yet neither of these spaces exceeds in direct distance six hundred miles. Then from the Volga to the Ural, which may be two hundred and fifty miles, we have twelve days; while the journey from the Ural to the inland sea of Balkash, or Palcati, occupied above forty-three days. Thus down to that point it required four months to travel not quite eighteen hundred miles. From the Balkash to Karakorum, the journey was performed in three

weeks. Is it possible to suppose that they could in that time have travelled fifteen hundred miles, the space which would be necessary to enable them to reach the Karakorum either of D'Anville or of Fischer? They could not have passed the great table plain of Soongaria, compared by the Oriental histories to a great sea of verdure, and consequently of all others the best fitted to form the central encampment of this great pastoral and military empire. All the geographical indications given by Rubruquis agree with this position; and disagree wholly with the other two. He says all the rivers observed by him flowed to the westward, which is true as far as Soongaria, but directly contrary to what takes place in the other positions, both of which are even placed upon rivers that flow to the eastward. China is said to lie to the south-east, as it does from Soongaria; but from the two other positions it would be directly south. The Kirghises are said to lie to the north, and the Baschkirs to the west; but these, according to the ordinary site, would have been at a distance quite immense, and could have had no relations with Karakorum. The hypothesis which places that city in Mongolia is founded upon the latter having been the original seat of Zingis; but Rubruquis expressly states, that this arrangement had now ceased, and that Tartaria was "the chief and royal city." Such a change was, indeed, almost necessary to an empire which was to embrace at once the East and the West; to hold China in one hand, and Russia in the other.

CHAP. V.

VENETIAN GEOGRAPHY.

172. *The republics of Italy, and above all that of Venice*, were the states in which the spirit of commerce and enquiry, after being long dormant, revived with the most brilliant lustre. The commerce which they carried on was one which connected them with the most distant regions: they traded in the jewels, the spices, and the fine cloths of India, a country situated at a distance really vast, and which then appeared almost immeasurable. It was not by Venetians, however, or by any Europeans, that the vast intervening space was traversed. They found the Indian commodities in the ports of the Mediterranean or the Black Sea, to which they were brought by the Arabs up the Red Sea, or by the interior caravans across central Asia. It was impossible, however, that they could see these precious and profitable commodities continuing to enter their ports, without feeling some curiosity as to the splendid and beautiful regions whence they came; and, in that age of enterprise, it was likely that some would be impelled to brave even the obstacles presented by this vast unknown space, occupied by people of a hostile and bigoted faith. The Abbé Zurla has collected notices of a considerable number who, actuated by this spirit of discovery, penetrated to a considerable depth into the interior of Asia. But the fame of all these is eclipsed by one, whose travels extended far beyond the rest, and who has always ranked among the greatest of discoverers of any age.

173. *Marco Polo* was a noble Venetian, whose family, like many others of the same rank, was engaged in extensive commerce. His uncles, Maffeo and Nicolo, had visited Tartary, and afterwards China, though without leaving any narrative of their observations. The pope, however, being apprized of their discoveries, sent out an ecclesiastical mission, accompanied by the young Marco Polo, then only nineteen. They spent twenty-four years in traversing the most remote regions of Asia. The result of their religious mission is not stated; but they returned laden with precious jewels, with which they dazzled the eyes of their countrymen, by whom they were not at first recognised. Marco being afterwards made prisoner by the Genoese, was persuaded to amuse the hours of confinement by dictating a narrative of his travels, which was read with avidity, and soon translated into all the European languages. He has suffered, like many other eminent travellers, under those injurious suspicions which arise in the minds of persons unwilling to believe any event or object which goes beyond the sphere of their ordinary experience. His name even furnished the nickname given to a personage introduced into the comedies of the age, to recite every species of extravagant fable. But modern information has verified in all its most essential points the narrative of Marco Polo, leaving only a slight tincture of that credulity which was characteristic of the age, and is confined to what was told him by others of countries which he did not himself visit. He appears to have first proceeded along the northern shore of Asia Minor, then the seat of a flourishing Turkish dynasty. He passed through Armenia, along the lofty ridges of Ararat, and descending the Euphrates through Curdistan came to Bagdad, no longer the capital of the caliphate, but still a flourishing and civilised city under its Tartar conquerors. He visited the great commercial capital of Ormuz, and thence proceeded eastward through the southern part of Persia by Kerman and Kubbees, across the great salt desert. At length he reached Balkh, which, though still a considerable emporium of central Asia, presented only in its ruined temples and spacious squares the vestiges of its ancient grandeur. Then passing along the borders of Cashmire and the mountain tract of Balashan (Budakshan), celebrated for its mines of rubies, he ascended to the elevated plain of Pamere, forming the summit of that cross branch of the Hemalleh, called the Beloor. On this, which appeared to him the highest ground in the world, he felt that difficulty in respiration, and in producing combustion, which is peculiar to the most elevated mountain sites. He afterwards reached the large Tartar cities of Yarkund and Cashgar, and entered on that great eastern table land which, before and since, has formed the *Terra Incognita* of Asia. He then entered Northern China, which he calls Cathay, and visited its capital Cambalu, his description of which strikingly coincides with that of the modern Pekin. He afterwards visited Mangi or Southern China,

and found in its capital, Quinsai, a scene eclipsing all that he had beheld either in Europe or in the East. It is described as a most immense, and, from its splendour and the beauty of its situation, almost a magic city. In fact Hangtchofoo, which corresponds, with Quinsai, though it has long ceased to be the capital of China, is still a very large city, very charmingly situated. From China, Marco Polo passed through the Indian Archipelago, hearing only of Great Java, but visiting Sumatra, which he calls Little Java. He touched at the coasts both of Malabar and Coromandel, and learned many particulars respecting India and its people, which have since been confirmed by modern observation. He returned by the Red Sea to Europe.

174. *A map of the world on a large scale, (fig. 14.) by Fra Mauro, which is preserved at Venice, and of which a highly finished copy exists in the British Museum, exhibits a view of the geographical ideas formed by the Venetians, founded upon the information derived from their Asiatic travellers, and prior to the discovery of America.*

BOOK III.

MODERN GEOGRAPHY.

175. *Geography was now to assume a new aspect*, and worlds before unknown were to be comprehended within her domain. Although the Italian states produced, almost exclusively, eminent astronomers, skilful pilots, and hardy navigators, their attention was nearly engrossed by land conveyance, and the navigation of the interior seas of Europe: they did not originate, or even attempt to follow, out any trains of oceanic discovery. The rulers of the exterior coasts of Europe, and especially of the Iberian peninsula, carried off all the prizes in this new and brilliant career. Between 1492 and 1498, the American continent, and the passage to India by the Cape, were discovered by Gama, and Columbus: the face of the world was changed; and all the daring and enterprising spirits of the age embarked in this career of discovery, conquest, and commerce.

CHAP. I.

DISCOVERY OF AMERICA AND THE EAST INDIES.

176. *The progress of discovery over the globe*, when the first steps had been taken, was astonishingly rapid; no cost, no peril, deterred even private adventurers from equipping fleets, crossing the oceans, and facing the rage of savage nations in the remotest extremities of the earth. Columbus had not yet seen the American continent, and the mouth of the Orinoco, when Cabot, of Venetian descent, but sailing under English auspices, discovered Newfoundland, and coasted along the present territory of the United States, probably as far as Virginia. In the next two or three years, the Cortereals, a daring family of Portuguese navigators, began the long and vain search of a passage round the north of America: they sailed along the coast of Labrador, and entered the spacious inlet of Hudson's Bay, which they seem to have mistaken for the sea between Africa and America; but two of them unhappily perished. In 1501, Cabral, destined for India, struck unexpectedly on the coast of Brazil, which he claimed for Portugal. Amerigo Vespucci had sailed along a great part of Terra Firma and Guyana, and he now made two extensive voyages along the coast of Brazil; services which obtained for him the high honour of giving his name to the whole continent. Grijalva and Ojeda went round a great part of the circuit of the coasts of the gulf of Mexico. In 1513, Nunez Balboa, crossing the narrow isthmus of Panama, beheld the boundless expanse of the Pacific Ocean. These discoveries afforded the impulse which prompted Cortez and Pizarro to engage in their adventurous and sanguinary career; in which, with a handful of daring followers, they subverted the extensive and populous empires of Mexico and Peru. Expeditions were soon pushed forward on one side to Chili, and on the other to California, and the regions to the north. Nearly a full view was thus obtained, both of the great interior breadth of America, and of that amazing range of coast which it presents to the southern ocean.

177. *In the Eastern world*, the domain which the papal grant had assigned to Portugal, discovery was alike rapid. Twenty years had not elapsed from the landing of Vasco de Gama, when Albuquerque, Almeida, Castro, Sequeira, Perez, and many others, as navigators or as conquerors, had explored all the coasts of Indostan, those of Eastern Africa, of Arabia, of Persia; had penetrated to Malacca and the Spice Islands; learned the existence of Siam and Pegu; and even attempted to enter the ports of China. But the characteristic jealousy of that power was soon awakened: the Portuguese embassy was not admitted into the presence of the emperor; and a mandate was issued, that none of the men with long beards and large eyes should enter the havens of the celestial empire. After all these discoveries, the grand achievement yet remained, of connecting together the ranges of eastern and western discovery; and of laying open to the wondering eyes of mankind that structure of the globe, which, though demonstrated by the astronomer, seemed to the generality of mankind contrary to the testimony of their senses.

178. *Magellan, in 1520, undertook*, by circumnavigating the earth, to solve this mighty problem: he passed through the straits which bear his name, and crossed the entire breadth of the Pacific. He himself was unhappily killed at the Philippine Islands, but his companions sailed on, and presented themselves to the astonished eyes of the Portuguese at the Moluccas. They arrived in Europe, after a voyage of three years; and it could no longer be doubted by the most sceptical that the earth was a spherical body.

CHAP. II.

EARLY SYSTEM OF MODERN GEOGRAPHY.

179. *The systematic arrangement of the immense regions* thus discovered, their adjustment to each other, and to the mass of knowledge previously possessed, was a task as yet beyond the resources of modern geography. It was to Venice that the results of discovery were still referred to be arranged and systematised; but the Venetian geographers, however skilful, laboured under many difficulties. The navigators seldom furnished them with any celestial observations, or even accurate surveys; for which, indeed, science had as yet provided no suitable instruments: they gave only rude delineations, on which the geographer was obliged to trace his uncertain way; most of the countries formerly known were touched at new points, and recognised under new names; and the continents, being made to contain both the old and the new features, were swelled to a preposterous magnitude. The east of Asia was obliged to contain at once the Serica of Ptolemy, the Mangi and Cathay of Marco Polo, and the China of the Portuguese, all as separate empires. The relative site of the two continents of Asia and America, the presentation of the west coast of the one to the east coast of the other, was of course the problem which they had the fewest means of solving. In a series of Venetian maps, preserved in the king's library, the two continents are described throughout their whole extent as either united, or separated only by the narrow Strait of Anian: the former delineation is retained even in a map by Bertelli, dated 1571; and in one by Cimertinus (1566), Cathay is placed upon the Gulf of Mexico. The expedition of Magellan, it might be supposed, would already have opened their eyes to the extent of that vast ocean which here intervened: but Magellan scarcely penetrated into the northern Pacific; and his ill-understood course was probably supposed to reach direct from Cape Horn to the Moluccas, which did not interfere with the hypothesis of the two continents meeting each other in a different latitude. The breadth of America, like all unknown spaces, was vastly exaggerated in the early maps; while eastern Asia, by the process above pointed out, was tripled in all its dimensions, and thus made to cover an ample portion of the Pacific.

180. *Sebastian Munster*, in 1572, produced a delineation of the world, which is cleared of some of the grossest mistakes, and which very tolerably delineates the general outline of the earth. He commits, however, a very discreditable mistake, in taking Ptolemy for his guide in regard to Scotland, and consequently representing that country as extending from west to east; a blunder the more singular, as his forms of Scandinavia and Ireland are liable to little exception. Singular flights of fancy are found in the works of these early geographers. Munster undertakes to describe, not only the surface of the earth, but also its interior: this is stated to be occupied by hell, a huge cavern two or three thousand German miles in length and breadth, and "capable of holding many millions of damned souls." Its existence was proved by the spirits which, in the depth of mineral caverns, as he had been assured by Cornelius Agrippa, often killed instantly a great number of men. The inflammatory gases, which are still frequently producing such disasters, afford certainly no unpalatable ground for that strange conclusion.

181. *Ortelius*, in the commencement of the sixteenth century, exhibits a remarkable improvement in geography. In his maps, all the parts of the globe begin to assume their real form and dimensions; America and Asia are widely separated, the expanse of the South Sea interposing between them. The south pole is invested with a *Terra Australis Incognita*; which, as it relates to New Holland, is said to rest on the authority of Marco Polo and Barthema, and in regard to the West, on that of Magellan. *Terra del Fuego* is made a portion of this Austral continent: while in lat. 41° S., and long. 10° west of Ferro, is *Promontarium Terræ Australis*. There is a *Terra Septentrionalis Incognita*, nearly as extensive, and seeming to include Nova Zembla. Greenland, however, exists distinct from it. In the interior of Asia, the Caspian, under the appellation of Mer de Bachu, presents the same form and dimensions as in Ptolemy, and receives all the rivers falling really into the Aral, the existence of which seems not to be suspected by this geographer.

182. *Mercator* advanced considerably farther, particularly by showing the imperfections of Ptolemy, and the injudicious manner in which the delineations given by him had been mixed with those furnished by modern authority. Mercator retains the Austral continent, including in it *Terra del Fuego*. The lakes of Canada appear for the first time in his maps, as a sea of fresh water, the termination of which is unknown. In Africa, Abyssinia, enormously amplified, is made the principal and almost sole feature; it extends southward to the vicinity of the Cape, comprehending Mozambique, and bordering on Caffraria: the Nile rises only about ten degrees north of the Cape, and consequently traverses all Africa from south to north. With respect to the extreme northern regions, this very learned man has indulged in some extraordinary flights of imagination. The ocean resumes, as in Homer, the character of a river, and is seen rushing by four mouths into the Polar gulf, to be absorbed, it is said, into the bowels of the earth. On one of the river branches are placed pigmies, scarcely four feet high; a notion suggested, perhaps, by the diminutive stature of the Laplanders and Sa-

moyedes : on another is placed a sort of northern paradise, while the Pole itself, a black and immense rock, towers to a prodigious height.

183. *From the time of Mercator modern geography* made rapid and continued progress, till it attained the state approaching towards perfection, in which it now exists : this will appear, when we consider it as astronomical, critical, or statistical ; and when we view it in its relation to the different quarters of the globe.

CHAP. III.

MODERN ASTRONOMICAL GEOGRAPHY.

184. *The astronomical geography* of the Greeks rested on a basis exceedingly narrow. M. Gosselin has, indeed, endeavoured to show, that they possessed a series of early and accurate observations, which they misunderstood and perverted ; but this point can scarcely be considered as established. It was only at Alexandria, Syene, Rhodes, and a few other leading points, that observations of latitude appear to have been made with a tolerable approach to accuracy ; all the others seem to have been only extended from rude itineraries. With regard to the longitudes, although the mode of calculating them by means of eclipses appears to have been understood, only one or two actual observations of this nature are recorded ; nor does it seem to have exerted any important influence on geography in general. The Arabs made much greater progress in this department ; but, through the separation produced by religious antipathy, their works were scarcely at all known in Europe at the period of the revival of letters. At that time, the pompous display of latitudes and longitudes made by Ptolemy, venerable as it had become from its antiquity, commanded universal assent.

185. *Modern observations* have gradually shown the magnitude of Ptolemy's errors. The first great shock to his authority was given by the latitude of Constantinople, which Amurath III. caused to be taken in 1574, when it proved to be two degrees lower than ancient authorities had assigned : the idea of such a difference, however, was treated with derision by some European geographers, till it was confirmed, in 1638, by Greaves, who had been sent to the East by Archbishop Laud. Even then, many, rather than renounce the authority of Ptolemy, believed that a change had taken place in the position of the earth ; but this notion became no longer tenable to any extent when Alexandria and other points were found very nearly to coincide with ancient observation. But the great alarm as to the unsoundness of ancient graduation was given in 1635, when M. de Peiresc caused an eclipse of the moon to be observed at Marseilles and at Aleppo ; and the difference of longitude, instead of 45° as it had been represented, was found to be only about 30° : such an enormous error, in a dimension which ought of all others to have been most exactly ascertained, shook altogether the blind confidence hitherto reposed in the longitudes of Ptolemy. It was at last perceived, that an entire reform of his graduations must be effected, before geography could rest on any secure basis. Numerous observations upon eclipses now began to be made ; but it was then discovered, that this only known mode of ascertaining the longitude was attended with many imperfections. In the observation of fifty-six eclipses, collected by Ricciolus, there were no two, observed in the same two places by the same men, which exhibited the same quantity of longitude : even the same eclipse gave different results, when observed at its four critical periods. As it was found impossible to guard against errors amounting even to three or four degrees, an opinion became prevalent, in the middle of the eleventh century, that unless for very great distances, even itinerary measures would give the result with greater accuracy ; yet Galileo, in 1610, had already pointed out a source of more accurate knowledge : he had in that year discovered three of the satellites of Jupiter, and in his *Nuncius Sidereus*, pointed out the use to which they might be applied. As his hints did not meet with the attention they merited, he communicated them more fully, in 1631, to Philip II. of Spain ; but that bigoted prince was unable to estimate their importance. Galileo met with a more favourable reception from the Dutch, who sent Hortensius and Bleau to Florence, to communicate with him on the subject. They found that great man involved in the storm of persecution which the ignorant bigotry of the Romish church had raised against him : he was thrown into prison ; and, after having asked pardon on his knees, for asserting that the earth moved round the sun, obtained only a mitigation of his confinement. This discovery was therefore of little use till 1668, when Cassini published his tables of the revolutions and eclipses of these satellites ; and three years afterwards, he and Picard made joint observations at Paris, and in the observatories of Tycho Brahe at Copenhagen, by which the longitude of these two important points, which had been the subject of long controversy, was finally fixed.

186. *The French government* now took the most active measures for extending geographical observation. Two academicians, Picard and De la Hire, were employed to construct a new map of France upon astronomical principles. In this operation they almost everywhere reduced the previous dimensions, which had been founded upon itinerary measures,

and were liable to their usual excess: they took off a whole degree from the western coast between Britany and Gascony, and half a degree from the coasts of Languedoc and Provence; so that on their return, Louis XIV. facetiously reproached them with having robbed him of a part of his kingdom. Other academicians were employed to determine the longitude of Goree on the coast of Africa, and of Guadaloupe and Martinico in the West Indies; and M. Chazelles was sent up the Levant on a similar mission. Expeditions on a much grander scale were despatched, under Maupertuis to the Arctic circle, and Condamine to the equator. The primary object of these was to determine the figure of the earth by the application of the pendulum; but the opportunity was taken of making various observations of longitude and latitude, in regions which had been formerly delineated only by processes of the most vague description.

187. *In the operation of determining the position of places* on the globe, important improvements have been made since the above eras. Although there can be no more accurate mode of determining the longitude, than by the eclipses of Jupiter's satellites, these are of too unfrequent occurrence to answer the practical purposes required. Observations of the transits of Mercury and Venus over the sun, of the occultations of the fixed stars, and of what are called lunar distances; processes, the nature of which will be fully explained in the following book, have been employed with success. Nay, to such perfection have chronometers been brought, that, by showing the difference of time between known and unknown points, they serve many of the ordinary purposes of navigation. The voyages undertaken by Capt. Cook, under the auspices of George III., afforded the means not only of exploring many islands and regions of the Pacific and Polar seas, but of throwing much light upon the general structure of the earth. The expeditions of Capt. Parry, and the nautical surveys executed under the direction of the British government by Flinders, King, Owen, and other officers, have gone far to fix the outlines of the great continents. The trigonometrical surveys of France and England, executed within the last thirty years, have almost completed the delineation of those countries. Still this branch of geography remains very imperfect.

CHAP. IV.

MODERN CRITICAL GEOGRAPHY.

188. *The application of a sound criticism to geographical materials* cannot be discerned in the rude and infant stages of the science. There is no branch in which the enquirer is so likely to be misled by false and fabulous rumours. The persons from whom he must draw his information, — the navigator, the merchant, the traveller, — make observations often only in a rough and superficial manner, and are swayed in their reports by fancy or vanity. The results of their own observation, or the authentic relations of well-informed persons, are confounded with the most vague rumours which float among the vulgar. Hence almost all the early systems have a portion of truth, mingled with many ideal and fabulous creations. The human mind unwillingly owns its ignorance even to itself. The geographer was reluctant to stop short at the point where his authentic information ceased. Having to delineate a kingdom or a continent, he filled up the really unknown parts from vague rumour, or a fanciful prolongation of those that were known. Whatever object had once found a place was copied mechanically without any enquiry, until modern maps and descriptions became crowded with objects, for the position of which no reason could be assigned.

189. *Strabo, among the ancient geographers*, was alone endowed with a critical spirit: but not having a sufficiently ample stock of materials, he exercised his judgment with a blind severity, which appears to have done injustice to several individuals whose exertions in the infant cause of discovery were highly meritorious. This extreme of scepticism, opposite to that of credulity, has indeed thrown unjustly into shade the merits of some of the most eminent discoverers, both ancient and modern. It is only by the collation of numerous authorities, accumulated by time and extended intercourse, that the just medium can be observed, and an equitable sentence pronounced on the reports of each party.

190. *D'Anville*, in the seventeenth century, possessed of ample materials, endued with indefatigable patience and sound judgment, undertook to revise the whole system, upon which the world and its regions had been hitherto delineated. The maps of the age were still covered with many obsolete and many fanciful particulars; and large portions of the world, concerning which absolutely nothing was known, were filled with imaginary cities and countries. D'Anville subjected every geographical feature to the strictest revision, and expunged without mercy those which rested on no positive and actual authority. The world, under his hands, assumed a new, and in some respects, a less flattering aspect. Maps, which had before been amply and regularly covered, now exhibited vast and unseemly blanks, which, amid the boasted learning of this age, implied a mortifying confession of ignorance. It was impossible, however, to deny, that this was the sound system upon which to proceed. Geography rested at last upon sure bases, and proceeded in a regular course of improvement.

191. *Major Rennell*, with a skill and sagacity not inferior to that of D'Anville, arranged and illustrated the mass of important materials collected respecting India and Africa; and, though additional contributions of vast importance have in some degree superseded his actual delineation, his example has introduced a still greater precision into the mode of treating the subject.

192. *The comparison of ancient and modern Geography*, and the tracing of the infant steps of early discovery, constitute an interesting field of enquiry, which has been much cultivated during the present age. Vossius, Bochart, and other learned scholars of the sixteenth century, had exercised much diligence in these researches; but they were not always guided by the soundest judgment, nor were they sufficiently acquainted with the objects actually existing, to be able to recognise them under the early descriptions. Rennell, Vincent, and Mannert, seem to have carried this research nearly as far as it can go, though without being able to dispel that impenetrable darkness in which some questions are still involved. Gosselin has applied to the science an extent of investigation, and a critical acumen, which, perhaps, none of his predecessors have equalled; but animated by too *Strabonic* a spirit, and seeking to subvert all the bases on which ancient geography had before rested, he has in many instances rather given lustre to bold and ingenious paradoxes, than made solid additions to the science.

CHAP. V.

MODERN DESCRIPTIVE AND STATISTICAL GEOGRAPHY.

193. *The mere outline of the globe*, its continents and countries, the leading features of mountains, rivers, and cities, their distance and position with respect to each other, constitutes all that in the very strictest sense can be called geography. But the mind cannot pass these in review, without feeling its interest excited, in even a superior degree, by other objects, for which these only serve as the basis. The productions of the earth, whether natural or artificial; the treasures hid in its bosom; the animals which roam or are bred on its surface; above all, the men by whom each region is peopled, — their manners, laws, industry, commerce, the revolutions through which they have passed, — these possess the strongest claim on our attention, and are of an importance superior to that of the mere geometrical outline.

194. *The ancients* did not occupy themselves with much more than the simple and fundamental bases of the science. The delineation of these formed alone an arduous task, which the geographer was required to accomplish before he could attend to the accessory and ornamental parts. Eratosthenes does not appear to have extended his research beyond those branches which were connected with astronomy. The work of Ptolemy forms a mere naked tabular list of positions, rarely enlivened by any historical or descriptive notices. Pliny does not go much farther. Strabo alone has enriched his work with numerous anecdotes and descriptions which, though not given on any complete or systematic principle, constitute a great portion of its value.

195. *Early modern writers* confined themselves, like the ancient geographers, to mere outlines. All the first treatises were formed on the model of Ptolemy; D'Anville, the head of the French school, applied himself solely to the boundaries and positions of countries, which he fixed with a precision before unknown, but without directing much attention to their physical and social relations.

196. *Statistics*, the science which treats of kingdoms and states in their relations of population, wealth, productions, commerce, and public force, is, as a separate branch of knowledge, only of recent origin. From the first it had a natural alliance with geography. Busching may be considered as the father of statistical geography: his vast research, strict fidelity, and access to the best sources, enabled him, in his description of Europe, to assemble a mass of information unequalled by any of his predecessors. He has arranged it, however, nearly in the same mechanical manner in which they had drawn the mathematical outlines of the globe. His writings, instead of conveying to the mind striking general views, are loaded with minute and burdensome details, which can be useful only as matter of reference, and would therefore have most properly appeared in the form of a dictionary. His successors have been numerous, and their labours are of similar character and value. Bruns, with regard to Africa, and Ebeling to Asia, continued the series. The great geographical work recently completed by Hassel, Cannabich, Gaspari, and Gutschmuth, in twenty-five octavo volumes, each equal to three or four of ordinary size, comprises, probably, the largest mass of statistical information ever assembled into one work.

197. *The English compilations of Bowen, Guthrie, Salmon*, and others of the same school, were, perhaps, the first works which embraced nearly all the objects that can give interest to a system of geography; and though indifferently executed, and devoid of any charms of style, they acquired a very extensive popularity. Mr. Pinkerton has executed a work on the same plan, in a superior manner, adding notices of the different branches of natural history,

and of the different languages of nations. M. Malte-Brun, by his acquaintance with the eastern and northern literature of Europe, and by an animated and interesting style, has produced a work in some respects superior. M. Balbi has distinguished himself by the industry with which he has collected geographical facts.

We shall now take a view of modern discovery in the remoter quarters of the globe.

CHAP. VI.

MODERN GEOGRAPHY OF ASIA.

198. *Asia* was the first continent which attracted the attention of Europeans, and the journies of all the early travellers. The enterprise of the Venetians penetrated into some of the wide and perilous tracts of its interior, which the boldest of more modern travellers have in vain essayed to reach. Since the passage of the Cape, the career of discovery has been chiefly maritime. We have seen how rapidly the Portuguese fleets explored all the southern coasts and islands. The eastern shores beyond Japan, as they presented nothing tempting to commercial avidity, were left to be examined by expeditions having science and curiosity for their object. This task was effected by Cook, Perouse, Broughton, and Krusenstern. Jesso, which had figured as a large continental tract, stretching between Asia and America, was reduced by them to its insular form and dimensions, and its separation from Saghalien established; the range of the Kurile islands was also traced; but some questions respecting this very remote and irregular coast remain yet to be solved. Along its northern boundary, beset by the almost perpetual ices of the polar sea, the progress of navigation was slow and laborious. The English and Dutch, the chief maritime states, made extraordinary efforts, and braved fearful disasters, in the hopeless attempt to effect by this route a nearer passage to India; but though they penetrated beyond Nova Zembla, they never could pass the formidable promontory of Severovostochnoi, the most northern point of the Asiatic continent. The Russians now claimed for themselves the task of advancing farther. They had most rapidly discovered, and conquered the whole south and centre of Siberia, and reached the eastern ocean at Ochotzk; but the frozen bounds of the north for some time defied their investigation. Proceeding in little barks, however, they worked their way from promontory to promontory. Behring and Tchirikof, early in the last century, sailed through the Northern Pacific, discovered the American coast, and the straits, bearing the name of the former, which divide Asia from America. Deschnew and Shalaurof, by rounding the Asiatic side of this Cape, and discovering the coast stretching away to the westward, were supposed to have established the fact of the entire separation of the two continents. There still remained a portion of coast on the side of Asia, which, it was alleged, might, by an immense circuit, have connected the two together; but the late voyage of Baron Wrangel seems to have removed every ground on which such conjecture could rest, and to have established beyond doubt or dispute, the existence of Asia and America as continents altogether distinct.

199. *Respecting the interior of Asia*, the British obtained much additional information from India, after they became undisputed masters of that region. This information was in many respects only a revival of ancient knowledge. The mountain boundary of India was traced, and found to rise to a height before unsuspected. The sources and early courses of the Ganges and the Indus, were found in quarters quite different from those which modern geography had long assigned to them. The mountain territories of Cabul and Candahar, the vast sandy plains of Mekran, were illustrated by the missions of Elphinstone and Pottinger; while Turner and Moorcroft penetrated into the high interior table land of Thibet. Recent and authentic information has also been acquired respecting Bochara and Samarcand, those celebrated capitals of the early masters of Asia: but there remains still a great central Terra Incognita, respecting which our information rests chiefly upon the desultory and somewhat clouded reports of Marco Polo, and the meagre narrative of Goetz; though some important and more precise information has recently been afforded by the researches of Humboldt and Klaproth.

CHAP. VII.

MODERN GEOGRAPHY OF AFRICA.

200. *Africa*, more than any other quarter of the globe, has defied the research, and humbled the pride, of modern enquiry. After accurate surveys had been made of the remotest oceans and shores, this continent, placed almost in view of Europe, still baffled every attempt to penetrate the mighty secrets which it held in its bosom. This vast and unbroken region, enclosed by huge expanses of desert, and occupied by barbarous and predatory tribes, for a

long period proved fatal to every daring mortal who attempted to penetrate into its depths. The Portuguese, however, at an early period, made very extraordinary exertions, impelled by the odd chimera of Prester John, a Christian prince, whom they expected to find in the interior. With this view they explored Abyssinia, of which they vastly exaggerated the dimensions, making them extend even to the Cape, in the vicinity of which, according to their idea, the Nile took its origin. In their progress also along the western coast, they sent repeated embassies into the interior, to discover, if possible, the abode of Prester John; and though that favourite object always eluded their search, they appear to have reached on one occasion as far as Timbuctoo, and learned at Benin some particulars respecting the great interior kingdom of Ogane or Ghana.

201. *The great interior river called by Ptolemy the Niger*, was the object which from the first excited the chief interest in respect to the African interior. All the early European navigators, on coming to the two broad estuaries of the Senegal and Gambia, concluded that one or both formed the termination of the long course which the Niger had been described as taking across the entire breadth of Africa. For several centuries the European nations, intent only on the trade in slaves, merely touched at different points of the coast, to which those unhappy victims were brought down by large caravans. In the beginning of the seventeenth century, however, the French and English having respectively settled on the Senegal and Gambia, were tempted, by the report and view of the gold brought from the interior, to push up these rivers and endeavour to reach Timbuctoo. They had not ascended far, when they became sensible that the extraordinary magnitude and distant origin ascribed to both was altogether chimerical. They were traced so near to their sources as to be little more than rivulets; yet still the explorers were far from Timbuctoo, and from the great central plain, through which the main course of the Niger was understood to flow. At the same time, notices were transmitted to the French geographers Delisle and D'Anville, which led them to infer that there was in that region another and greater river, which flowed eastward towards the interior, and of which they were unable to learn the termination. Yet this delineation of these great geographers had been in a great measure lost sight of, even among their own countrymen.

202. *The information obtained by the African Association* at first tended to confirm this impression. The persons who had crossed the Niger at the most eastern part of the central African plain, described it to Mr. Lucas as flowing westward: but these conflicting statements were silenced by the first expedition of Mr. Park, who at Sego beheld it a broad and majestic stream, flowing through the plain of Bambarra from west to east, and directing its course into the depths of interior Africa. From that time, the termination of the Niger became the grand problem which the science and the enterprise of the age were exerted to solve. A boundless field was open to conjecture. By one theory, the Niger was lost in some great inland seas or lakes of the interior; by another, it bent to the south and west, and reached the Atlantic either in the gulf of Benin, or by the estuary of the Congo; lastly, it rolled to the eastward, till, under the name of the Abiad, or White River, it became the principal head of the Nile of Egypt. At last, by the persevering exertions of the British government, an expedition fairly succeeded in penetrating into the hitherto unknown interior of Africa, and in throwing a wonderful addition of light upon its structure. This mission, however, broke up the grand question. They discovered, flowing through the great African plain, not one river in one direction, but several in different directions; all of which, it appears, have been considered at different times, and under different circumstances, as the Niger. These rivers are four:—

1. The Senegal, considered by the Arabians and modern Europeans as the embouchure by which the Niger entered the ocean.
2. The Joliba, which ever since it was visited, and its course ascertained, by Park, has been fixed in the mind of Europeans as the only Niger; though I question if it was known to any of the ancient geographers who used that term. The termination of this river is yet unknown.
3. The Quarrama, or river of Zirmie, first discovered by the late mission, flowing from east to west, and falling into the Joliba or Quolla. This is evidently the Arabian Nile of the negroes, on or near which are situated all their great cities—Ghana, now known under the name of Cano; Berissa, under that of Bershee; Tocrur, as I apprehend, under that of Sackatoo.
4. The Yeou, flowing eastward into the great lake of Bornou, and which appears to have been the western Nile of Herodotus, visited by the Nasamonian adventurers from Tripoli. The mission also ascertained the site of the kingdom of Bornou, which had been very erroneously placed; they discovered the fertile kingdom of Loggun, perhaps the Cauga of Edrisi, and the great mountain region of Mandara, which appears to be the *Mons Mandrus* of Ptolemy. The subsequent expedition of Clapperton from the Gulf of Benin showed the connection between the Atlantic coast and the interior, and completed the diagonal section made across the greatest breadth of the African continent. It showed also the continuity of large and populous kingdoms extending in this direction: Eyeo, the Gago of Leo and the early geographers; Zegzeg, with its large capital Zaria; Nyffé, the most industrious of the African states; Boussa, Koolfu, and other flourishing cities. The Niger of Park was here seen holding a southerly direction towards the Gulf of Benin; but it was reserved for Landers finally to solve the grand

problem by tracing the Niger down to its termination in the Gulf of Benin. This discovery, with that of its numerous tributaries, opens to British commerce the prospect of being able to penetrate into the most interior and finest regions of the African continent.

203. *Among partial but important contributions to the knowledge of Africa, may be mentioned the observations of Bruce and Salt in Abyssinia; those of Brown in Darfur; of Waddington and Caillaud in the upper part of the Nile; and, lastly, of Lichtenstein, Campbell, and Burchell, upon the countries which lie in the interior northward from the Cape of Good Hope.* Yet a vast field still remains for future discovery. In particular, all the southern interior, from the equator nearly to the Cape, has scarcely been the subject even of rumour. The sources of the Nile, after the search of so many ages, are yet unexplored; as well as that wide range of territory which intervenes between it and the series of rivers which we have just noticed as assuming the name of Niger. The continuity and structure also of that vast chain of mountains, which, according to recent travellers, appears to cross Africa at its greatest breadth, and gives rise to so many mighty streams, has yet by no means been completely traced.

CHAP. VIII.

MODERN GEOGRAPHY OF AMERICA.

204. *The discovery of America, as formerly observed, was made in the first instance with extraordinary rapidity.* The thirst for gold and the spirit of adventure urged nation after nation to explore its coasts, and penetrate its interior. Within twenty years was formed a full and tolerably precise outline of the whole western coast, from the mouth of Hudson's Bay to the Straits of Magellan. The conquests of Cortez, of Pizarro, and of their immediate successors, soon conveyed a pretty accurate idea of the western coast of South America, of Mexico, and even of the peninsula of California. But the northern regions, stretching into the ices of the Pole, presented barriers of a formidable description, which long baffled the utmost efforts of navigators. America on this side resisted for a longer time the attempts to complete its delineation than any other continent.

205. *To explore the North-western coast seems to have been an undertaking properly belonging to Spain, the possessor of all the vast and opulent regions which extend along the Pacific.* Recent notices have shewn that they did not altogether neglect that enquiry, for Cortez and several of the other viceroys sent expeditions along this coast, to which they gave the name of New Mexico. The Spaniards, however, as usual, shrouded in deep mystery even these limited discoveries, and were long able to prevent the other nations of Europe from visiting this coast, the most remote and inaccessible of any in the circuit of the globe. Europeans, therefore, were not aware of the vast breadth to which this continent expanded towards the north. They rather supposed that, like South America, it narrowed to a point or cape, upon passing which the navigator would enter upon the expanse of the Pacific, and might bear down upon Japan, China, and the East Indies. The commercial nations therefore made vigorous and almost ceaseless efforts to turn this point, and effect, as they imagined, a nearer and more direct route into the eastern seas.

206. *The English took by much the most decided lead in this important career.* Under the reign of Queen Elizabeth, Frobisher and Davis made each three successive voyages. One discovered the entrance into Hudson's Bay, the other found the entrance into the great sea which bears the name of Baffin's Bay; but, partly arrested by the well known obstructions to which these seas are liable, partly diverted by a chimerical search after gold, they could not penetrate beyond the numerous islands and inlets by which these entrances are beset. Hudson, in 1610, steered a bolder course, and entered the vast bay, which has received its appellation from that great navigator, who there unfortunately terminated his adventurous career. The treachery of a ferocious and mutinous crew exposed him on these frozen and desolate shores, where he miserably perished. Sir Thomas Button followed in 1612, and finding himself in the middle of this capacious basin, imagined himself already in the Pacific, and stood full sail to the westward. To his utter dismay he came to the long continuous line of shore which forms the western boundary of Hudson's Bay. He expressed his disappointment by giving to the coast the name of "Hope checked." Bylot and Baffin, who followed three years after, were stopped by the ice at Southampton Island. Baffin, however, made afterwards a more important voyage, in which he completely rounded the shores of that great sea which bears his name, and which, appearing to him to be inclosed on all sides by land, has been denominated Baffin's Bay. The error involved in this appellation deterred subsequent navigators from any further attempt; for Baffin, in passing the great opening of Lancaster Sound, had concluded it to be merely a gulf. From that period the English navigators, though they ceased not to view this object with ardour, hoped to fulfil it only by the channel of Hudson's Bay. In 1631, two vessels were sent thither under Fox and James.

The latter, entangled in some of the southern bays, returned after dreadful sufferings from the cold of the winter; but the former, quaintly calling himself North-west Fox, explored a part of that great opening called Sir Thomas Roe's Welcome, which appeared now to afford almost the only hope of a passage; but he stopped short at a point which he termed "Fox's farthest." Under Charles II. a company was formed for the purpose of settlement and commerce in Hudson's Bay, and engaged to make the most strenuous exertions to discover a western passage; but it is believed that the only exertions really made by the Company tended to prevent any such discovery. Middleton, an officer in their service, was sent out in 1741, sailed up the Welcome, and believed himself to have discovered that the head of that channel was completely closed. He was strongly charged with having received a high bribe from the Hudson's Bay Company to stifle the discovery, and Moor and Smith were sent out in the following year with the most sanguine hopes; but when they returned without having effected any thing, the public expectations were greatly abated. It became the general impression that America, on this side, formed a mass of unbroken land, and that the long sought passage had no existence.

207. *New views of the extent and form of the northern extremities of America* were opened by the discoveries of Cook, corroborated by those of some other English navigators in the Northern Pacific. It appeared that America there stretched away to the north-west, till it reached a breadth equal to one fourth part of the circumference of the globe. Cook penetrated, indeed, through the strait which bounds the continent and separates it from Asia; but the coast appeared there extending indefinitely north; and it became a general impression that America formed a huge unbroken mass of land approaching the Pole, and perhaps reaching that ultimate point of the globe. This belief received a sudden shock from Hearne's voyage down the Copper Mine River, and his discovery of the sea into which it fell, in a latitude not higher than that of the north of Hudson's Bay. Soon after, Sir Alexander Mackenzie traced also to the sea another river twenty degrees farther west. There was now a strong presumption that a sea bounded the whole of America to the north, and that there really was such a passage as had been so long sought, and might be found, were it not too closely barred by ice and tempest. The British administration, animated with an active and laudable zeal in the cause of discovery, determined that no possible effort should be omitted by which this important and long agitated question might be brought to a final decision.

208. *A series of exploratory voyages was now begun.* Capt. Ross, in 1818, made the circuit of Baffin's Bay, and returned with the belief that no opening existed: Lieut. Parry, second in command, formed a different judgment, and having satisfied the Admiralty as to his grounds of belief, was sent out with the command of a new expedition. In this memorable voyage, Capt. Parry penetrated through Lancaster Sound, which he found to widen gradually, until it opened into the expanse of the Polar Sea. He did not touch on any part of the American coast, but found parallel to it a chain of large islands; and his progress through these was arrested, not by land, but by straits and channels encumbered with ice. In consideration of these obstacles, his next attempt was made through Hudson's Bay, by the yet imperfectly explored channel of the Welcome. Struggling through various obstacles, he reached at length a point considerably beyond that where Middleton had stopped, and found a strait opening from Hudson's Bay into the Polar Sea. This strait was, however, so narrow, and so completely blocked with ice, that there appeared no room to hope that it would ever afford an open passage. Capt. Parry was therefore again sent out in his first direction; but he made no material addition to his former discoveries. Meantime a land journey, under Capt. Franklin, following in the footsteps of Hearne, reached the sea, and discovered a considerable extent of the hitherto unknown northern coast of the American continent. A tolerably clear glimpse was thus obtained of its extent and boundaries; and the zealous efforts of government were employed to verify the whole by actual survey. A second expedition under Capt. Franklin extended this survey over three fourths of this boundary coast, and reached beyond the 146th degree of longitude. Meantime an expedition, under Captain Beechey, sent to meet Captain Franklin from the westward, passed the Icy Cape of Cook, and arrived at nearly 156° W. longitude; between which point and Captain Franklin's farthest limit there intervened only 7°, or 160 miles.

209. The belief was hence entertained, that the whole coast extended in a line not varying much from the 70th degree of latitude; but the important expedition, which Captain Ross has just achieved through so many difficulties, proves the existence of a large peninsula, extending as far north as 74° N. latitude. It remains still probable that a naval passage may exist farther north, in the line of Captain Parry's first voyage. But the encumbering ice is so thick, and so wedged into various straits and channels, that probably no vessel will ever be able even once to work its way through; and certainly a ship could never set out with any assurance of thus finding its way from the Atlantic into the Pacific. Britain has, however, reaped an ample share of glory in contributing so essentially to delineate the boundaries and dimensions of this great and important continent.

CHAP. IX.

MODERN GEOGRAPHY OF THE AUSTRAL SEAS AND ISLANDS.

210. *More than half the surface of the globe, including long groups of islands and vast expanses of ocean, remained unexplored, even after regular naval routes had been formed round the Cape of Good Hope, and Cape Horn; yet there soon arose the belief of an Austral continent, as extensive and as abounding in wealth as that which had been discovered by Columbus. An ideal balance was fancied, which it was supposed must exist between the lands of the northern and those of the southern hemispheres; and the more disproportionate the extent of sea which existed in the known parts of the latter, the greater it was supposed must be the mass of southern continent which was to establish this ideal, imaginary balance. In all the early maps, a huge continental mass encircles the Antarctic pole, and presents to the great ocean a continuous circuit of shore reaching round the globe: the above analogies were doubtless aided by discoveries made on great insular tracts of the South Sea, so partial that they might be mistaken for promontories, or portions of a great mass of Antarctic land.*

211. *The Portuguese, so long the most skilful and intrepid navigators of the ocean, appear to have been the first who threw any light upon this fifth and most remote portion of the earth: in less than twenty years after their passage of the Cape they had reached the most extreme islands of the Oriental Archipelago, including Java and the Moluccas, and appear even to have observed some parts of the coast of New Guinea. There are no records of their having proceeded farther; but maps have been found in the British Museum, and other collections, which exhibit an extensive land to the south of Java, under the title of Java Major, on which occur a number of names, some of them Portuguese: one of these maps, partly translated into French, has the "*Côte des Herbages*," a name somewhat curiously coinciding with Botany Bay. None of these discoveries, however, have been embodied in any known narration.*

212. *The Spaniards also, during their early and adventurous career, made strenuous efforts to explore the southern seas: Magellan, as already observed, by his first circumnavigation of the globe, effected a grand step in geographical discovery. Alvaro Mendana, in 1568, sailed from Lima, and, after crossing the breadth of the Pacific, discovered a group of large maritime lands, to which, from a chimerical reference to Ophir, he gave the name of "Islands of Solomon:" they appear to be part of that great group which forms the outer range of Australasia. Mendana set out on a second voyage, and reached the same quarter, but, by some fatality, could not again find the islands formerly discovered. Quiros made a still more important expedition: he passed through the Polynesian group; and Sagittaria, one of the islands discovered by him, appears clearly identified with Otaheite: he terminated his voyage, like Mendana, among the exterior islands of Australasia; and with him expired the spirit of Spanish enterprise.*

213. *The Dutch, when they had expelled the Portuguese from Java and the Spice Islands, and had established in them the centre of their Indian dominion, were placed in such close proximity with New Holland, that it was scarcely possible for a great maritime nation to avoid extending their search to that region. Van Diemen, the Dutch governor of India about the middle of the seventeenth century, greatly promoted this object, and sent successive vessels to explore the coast of New Holland. Hertog, Carpenter, Nuytz, and Ulaming made very extensive observations on the northern and western shores, but found them so dreary and unpromising, that no settlement of any description was ever attempted. Abel Tasman, however, went beyond his predecessors; he reached the southern extremity of this great mass of land, to which he gave the name of Van Diemen, without discovering it to be an island: he then sailed across, surveyed the western coast of New Zealand, and returned home by the Friendly Islands. This important range of discovery was not followed up; it refuted, however, the delineation by which New Holland had been made part of the imagined Austral continent. In the newly arranged charts, that continent still remained, but with its position shifted farther to the south, and New Zealand probably contributing to form part of its fancied outline.*

214. *The English nation, by the voyages of several navigators, and particularly of Cook, secured the glory of fully exploring the depths of the great Pacific. The previous voyages of Byron, Wallis, and Carteret had already made known some of the interesting groups of islands with which its vast surface is studded. Cook fully traced the great chains of the Society Islands, and of the Friendly Islands; he discovered and surveyed the eastern coasts of New Holland and Van Diemen's Land. He settled the form and relations of New Zealand, New Caledonia, and the other great Australasian lands and islands. This side he passed thrice the Antarctic circle, and ranging along the yet unvisited borders of the southern pole, solved, by refuting, the famous modern hypothesis of an Austral continent. He navigated also through the northern Pacific, observed carefully the group of the Sandwich Islands, and established, in the manner before pointed out, the relation between the continents of Asia and America. Many eminent navigators, among the French, La Perouse, Marchand,*

D'Entrecasteaux; among the Russians, Kotzebue and Krusenstern; among the English, Vancouver and Beechey, followed; and, though the grand prizes of discovery had been carried off, found still some gleanings in so vast a field. The circumnavigation of the globe has ended in becoming a mere trading voyage, which conveys neither name nor glory to him by whom it is achieved. Captain Weddell, however, has lately, in New South Shetland, found a tract of land situated nearer to the Antarctic pole than any previously supposed to exist.

215. *New Holland*, much the most extensive of the lands belonging to the southern hemisphere, and rendered doubly interesting by its recent relations with Europe, has formed the theatre of the latest southern discoveries. Mr. Bass, in an open boat, found the strait which bears his name, separating New Holland from Van Diemen's land, and making the latter a separate island. Baudin and Flinders, contemporaneously employed by the French and English nations, made a continuous survey of the vast circuit of its coasts, which had been before touched only at partial points. At a later period, Freycinet made some additional observations; and King found still a great extent of north and north-western coast to survey for the first time. More recently, the discovery of Swan River and its shores promises to redeem the reproach of sterility which had been attached to the whole western coast of this continent: the interior on the eastern side also, though guarded by steep and lofty barriers, has, through the exertions of Mr. Oxley and others, been penetrated to a considerable depth, and found to contain extensive plains traversed by large rivers. Still the explored tracts form only a small proportion of the vast surface of this southern continent.

PART II.

PRINCIPLES OF GEOGRAPHY.

216. *Among the various branches of human knowledge* there is so intimate a connection, that no science can be truly said to be independent of all others. Some, indeed, may be regarded as primary, because, to a certain extent, they have had an independent existence, and because other sciences have sprung from them. Such, for example, are arithmetic and geometry, the prolific parents of all the branches of modern mathematics. Other sciences, again, are connected by collateral relationship, in respect of their affording mutual aid: and in this manner all the branches of human knowledge depend one on another, each repaying the advantages which it has received.

217. *The subject of this treatise*, GEOGRAPHY, which in common with other sciences owes its origin to the wants of man, joined with his inherent desire of knowledge, has arrived at its present state of improvement by the aid of several sciences, and of a very great number of the arts which are the fruit of human ingenuity. It is more particularly indebted to the mathematical sciences, either directly, as furnishing rules and methods by which the magnitude of the earth, its figure, and the position of the different parts of its surface, may be determined; or indirectly, inasmuch as it has been improved by astronomy, navigation, and other sciences which owe their perfection to the mathematics. To the arts its obligations are innumerable: for every step of progress which has been made in the construction and management of ships, in the fabrication of mathematical, optical, and nautical instruments, and in the collateral arts on which these depend, has contributed to the advancement of geographical knowledge.

218. *The doctrines of geography* strongly support, and have a close affinity with, those of astronomy. It is only by the application of this latter science that we have been able to discover the true figure of the earth, and its magnitude: and some of the most important divisions of the earth's surface are marked out by astronomical phenomena. On the other hand, an exact knowledge of the figure and magnitude of the earth is of the highest importance in the explication of the more recondite doctrines of astronomy. Hence, while the doctrines of astronomy involve the principles of geography, it holds equally true that the principles of geography can only be understood by a due application of some of the more simple theories of astronomy.

219. *The science of geology* has, if possible, a still more intimate connection with the description of the earth. While astronomy delineates the form and movements of that planet, and its relation to other bodies in the universe, geology describes the materials which compose its surface, and the order in which they are arranged, with the composition and phenomena of the surrounding atmosphere. The various inequalities into which it is formed, the distinction of land and sea, with their origin and effects, come all within the sphere of this important science.

220. *The organised and living beings* which cover the surface of our planet, form a most interesting feature in its delineation. For the support and nourishment of these, the whole

of its vast structure was originally destined. In taking a survey of this interesting range of objects, we may begin with plants; then ascend to animals; and, lastly, to man, who holds the chief rank in the constitution of this lower world.

221. *Three divisions, comprehending each a separate book, will, on the grounds now stated, comprehend the Principles of Geography: these are — I. Astronomical Principles. II. Geological principles. III. Geography considered in relation to the organised living and rational natures which cover the surface of the earth.*

BOOK I.

ASTRONOMICAL PRINCIPLES.

CHAP. I.

GENERAL VIEW OF THE PHENOMENA OF THE HEAVENS, APPARENT MOTIONS, FIXED STARS, PLANETS, &c.

222. *The succession of day and night brings under our observation the sun, the moon, and an innumerable multitude of luminous bodies, which appear like points on the concave surface of the heavens. Of these the sun and the moon are the most remarkable. The sun at all times presents to us a circular disc: the disc of the moon is also at certain periods circular, but she undergoes a succession of changes in the appearances of her luminous part, which are denominated phases. With regard to the distances of the sun and moon from this earth, we are certain that they are very remote; for we observe that their apparent magnitude is not sensibly affected by any change in our local position. We may with probability suppose the stars to be bodies of the same nature with the sun and moon, appearing smaller only because they are at a greater distance.*

223. *The apparent motion of the heavens from east to west about a fixed point in the northern quarter of the sky, as seen in this country, is a phenomenon quite familiar to every one. If we change our position on the earth by going always south, this fixed point appears to descend, and at last it sinks below the horizon: but we now perceive that there is another fixed point in the southern region of the heavens, exactly opposite to the former, about which the diurnal motion is also in like manner performed. These two points are the NORTH and SOUTH, or the ARCTIC and ANTARCTIC POLES of the heavens.*

224. *From what we see on the earth's surface, we learn by experience that the real and apparent motions of bodies may be very different. An observer in a vessel carried along by the current of a river, will feel disposed to believe himself at rest; and then, if he were to judge from appearances, he would suppose that trees and fixed objects on the banks were in motion, because of the apparent change in their relative positions. Hence we may infer, that we cannot judge immediately respecting the absolute motions of the heavenly bodies from their apparent motions. It has only been by a series of nice observations, and the application of the doctrines of mathematics, that the former have with absolute certainty been deduced from the latter.*

225. *The general phenomena of the apparent motions have, however, been discovered by the ordinary observation of mankind from the remotest ages. To a spectator in any place of the earth, the whole system of the celestial bodies appears as if placed on the surface of a concave sphere, the centre of which is the place where he stands; and this sphere appears to revolve daily on an ideal line which passes through the poles of the heavens, and is called the AXIS of the world. Although the supposition that the celestial bodies are all situated in the surface of a sphere, of which the eye is the centre, be perfectly consistent with the appearance of the heavens, it is easy to understand that this may be a consequence of their immense distances. To an observer standing on an extensive plane, objects very remote around him, though at unequal distances, would appear in the circumference of a circle having his eye in the centre.*

226. *Besides the diurnal motion of the heavenly bodies, which is common to them all, we discover that some of them have peculiar motions by which they change their apparent places in respect of one another. Thus we see the MOON in the course of about a month describe a circle quite round the heavens from west to east. The SUN also appears to change his position daily, and to go round the heavens from west to east in a year. It is in consequence of this peculiar motion of the sun, that we find different stars at different seasons of the year set immediately after him, or rise immediately before him; and that the appearance of the heavens through the course of the year is continually changing.*

227. From the remotest antiquity *five* stars had been observed to change their position ; and in modern times five others have been discovered. These "wandering stars" have been appropriately denominated PLANETS ; and, generally speaking, they can be seen at all times, except when their feeble light is rendered insensible by the effulgence of the sun. The planets have received particular names, and are distinguished by particular characters ; these are Mercury ☿, Venus ♀, Mars ♂, Vesta ♄, Juno ♃, Ceres ♄, Pallas ♀, Jupiter ♃, Saturn ♄, Uranus ♅.

228. *There are other luminous bodies* having a proper motion, which are seen for a short time and afterwards disappear. Their existence, however, is permanent. They are distinguished from the planets by their being visible only for a short period, and also by a train of light proceeding from them on one side, forming a *tail* ; these bodies are called COMETS. Their number is not known, but it appears to be very considerable.

229. *Besides the sun, moon, planets, and comets*, there are other luminous bodies visible every clear night ; these retain always the same position in respect of each other, and for this reason are denominated FIXED STARS. Their apparent motion about the axis of the celestial sphere is perfectly uniform, and a complete revolution is performed in about 23 hours 56 minutes.

230. *By the permanence of the relative situations of the fixed stars* on the concavity of the celestial sphere, we are enabled to determine the apparent motions of the other heavenly bodies. Of these the motions of the sun and moon are the most conspicuous and simple. The motions of the planets appear more complicated, and are considerably different from one another. This dissimilarity might well lead to a conjecture, that the real motions of the heavenly bodies are very different from the apparent motions, and that these last are modified by the real motion of the earth. This conjecture we shall afterwards find fully verified.

231. *All the heavenly bodies* which this general survey has brought under our notice, with their motions and mutual relations, form the subject of ASTRONOMY, which of all the natural sciences presents the most extensive series of discoveries. By observing for ages, and determining with exactness the positions of the sun, moon, and stars ; by tracing and measuring with precision their various motions ; and by employing all the resources of mathematical science in investigating the constant laws to which these motions are subject, the human mind has succeeded in passing from the first cursory view of the heavens, to that comprehensive survey by which, in the present state of astronomical science, we contemplate the past and future states of the system of the universe.

CHAP. II.

THE HEAVENS AS SEEN THROUGH THE TELESCOPE.

232. *From the discovery of the telescope*, and its application to the purposes of astronomy, a new era may be dated in that science. The number of stars visible to the naked eye is about three thousand, which appear scattered over the concave surface of the heavens. Even in the clearest night, and in the absence of the moon, seldom more than two thousand are seen at once. They are not distributed indiscriminately over the heavens, but are disposed in groups, which from the remotest antiquity have received distinct names, and these have been employed to facilitate the description of the heavens, and the reference to any particular star. The ancients imagined the figures of various personages of their mythology, and of animals, &c. to be traced on the concave surface : these figures they called *constellations*, and considered a group of stars to belong to each. To some of the brighter stars, and to those more remarkable for their position, proper names have been given.

233. *The distinction founded on the different degrees of brightness* of the fixed stars, is the most obvious which occurs to the spectator while his vision is unassisted by the telescope, and has, accordingly, been employed for the purpose of classifying them. The stars visible to the naked eye have been, on this principle, arranged under six *magnitudes*. The brightest are reckoned to be of the first magnitude, the next in brightness of the second, and so on to the sixth magnitude. The arrangement of the stars has been still farther facilitated by combining the principle of this last-mentioned arrangement with the method of constellations. In maps of the heavens and on celestial globes the constellations are delineated, and the stars in each constellation are marked with the letters of the Greek alphabet according to their degrees of brightness.

234. The use of the telescope has greatly increased *the number of visible stars* ; and has at the same time discovered to us many particulars before unknown respecting those that are visible to the naked eye. Many of the stars which to unaided vision appear single, are found, when observed through a telescope of high magnifying powers, to consist of two, sometimes of three or more stars extremely near to one another. Seven hundred of these

multiple stars were observed by Sir William Herschel, and the number has been increased by the joint labours of his son and Sir James South, also by the German astronomer Struve. In some of them the small stars are different in brightness and in the colour of their light. Thus α Herculis is double; the larger of the stars is red, the smaller blue: ϵ Lyrae is composed of four stars; three white, and one red: γ Andromedæ consists of two stars very unequal, the largest a reddish white, the smallest a sky-blue inclining to green. Some single stars evidently differ in their colour: Aldebaran is red, Sirius of a brilliant white.

235. *Nebulæ* are small luminous spots of a cloudy appearance and irregular shape, seen in many places of the heavens. The most remarkable appearance of this kind is the Galaxy, or Milky Way, which encompasses the whole heavens, and is visible to the naked eye. The Sword of Orion contains a beautiful nebula. Two occur in the head of the Great Bear, one of an oval shape, the other round like a comet without a tail. Viewed through a telescope of great magnifying power these luminous spots are resolved into a multitude of small stars, distinctly separate, but apparently very near one another, whose light being blended together produces the luminous appearance. In a portion of the Galaxy, about fifteen degrees in length, and two in breadth, Dr. Herschel found no fewer than fifty thousand stars large enough to be distinctly counted. The number of *nebulæ* is very considerable, Herschel discovered two thousand; before his time only one hundred and three were known.

236. Continued observation has shown that *the fixed stars are not altogether exempt from change*. Several stars mentioned by the ancient astronomers are no longer visible, while some are now seen by the naked eye which are not in the ancient catalogues. Some stars have suddenly appeared, and after having been seen for a short time have ceased to be visible. In 1572 a new star appeared in Cassiopeia's Chair; and in 1604 another appeared in Serpentarius. These stars did not change their places: but having gradually increased in brilliancy, until they exceeded Venus or Jupiter in brightness, and were even seen in the day-time, they diminished in the same gradual manner, and in a few months entirely disappeared. Some stars are observed to have periodical changes of brightness. Of this description is Algol, or β Persei: when brightest it is of the second, and when least bright of the fourth magnitude. It goes through all its changes of lustre in four days, twenty-one hours. Other stars, like β in the Whale, have gradually increased in brilliancy; or, like δ in the Great Bear, have continually diminished in brightness.

237. *The fixed stars*, when viewed through the telescope, appear like luminous points on the concave surface of the heavens; but the planets are found to exhibit the appearance of discs of greater or less diameter. Mercury and Venus accompany the sun, appearing at one time on the east, and at another time on the west of that luminary, and never receding from him beyond a certain distance. The other planets recede from the sun to all possible angular distances. Connected with this circumstance is a distinction which it is useful to make of *inferior* planets and *superior* planets; the former appellation being applied to Mercury and Venus, and the latter to the remaining planets.

238. *Mercury and Venus*, as they oscillate about the sun, exhibit all the phases of the moon. From having the appearance of a crescent they gradually assume that of the half moon. The illuminated part of the disc increasing, they become gibbous, and at last present a complete circular disc, like the full moon. From this state of illumination they again pass through the same appearances in an inverted order, until they disappear altogether. Sometimes these planets are seen like black spots in the sun; these appearances are called *transits* of the planets over the sun's disc. They are rare, but when observed, particularly the transit of Venus, they give the best means of determining the magnitude of the solar system. In all the phases of Mercury and Venus the convexity of the illuminated portion of the disc is turned towards the sun.

239. *The discs of the other planets* are always nearly circular. Mars, however, in certain positions with regard to the sun, assumes a gibbous appearance; but he never becomes cornicular like Venus. He has no satellite. As viewed from the earth, he is known by his red and fiery appearance. Dr. Herschel observed that the polar regions of Mars, after having been turned from the sun, appeared brighter than the rest of the planetary disc; just as if these regions had in the absence of the sun's heat been covered with snow.

240. *Certain spots appear* on the discs of the sun and the four planets Venus, Mars, Jupiter, and Saturn, when they are viewed through the telescope, and are distinguished from other parts of the discs by the colour or intensity of their light. Similar spots are seen on the moon with the naked eye. Jupiter has also his disc marked with several parallel belts or stripes, which stretch across it. They are subject to considerable variation with regard to number, breadth, and distance from each other. Mercury is too much immersed in the solar rays; Vesta, Ceres, Juno, and Pallas are too small; and Uranus is too distant to allow points of unequal brilliancy to be observed on their surface. The spots upon the sun are very variable in their number, position, and magnitude. Often they are numerous, and of great extent. Each of them, in general, consists of a dark space, or *umbra*, surrounded by a *penumbra*, or fainter shade, beyond which is a border of light more

brilliant than the rest of the sun's disc. Sometimes, though seldom, the sun has been without spots for several years: this was the case from 1676 to 1684. The dark nucleus of the spot is seen to form and disappear amidst the greater brilliancy that surrounds it. After the nucleus ceases to be seen, the umbra continues visible for some time: the place where it at length disappears becomes like the other parts of the solar surface, unless it be succeeded, which is sometimes the case, by a luminous spot. Umbrae of great extent have, with few exceptions, a nucleus in their centre; but small umbrae are often seen without it.

241. *The solar spots* are never stationary, but are seen to move slowly over the sun's disc from east to west. Their paths across the disc, when accurately traced, are found to be rectilinear in the beginning of June, and in the beginning of December; but in the intermediate seasons they are found to be elliptic. Between June and December the convexity of the path is towards the upper part of the disc, and between December and June it is towards the lower part.

242. *The planet Jupiter*, when viewed through the telescope, appears to be attended by four small stars, ranged nearly in a straight line, which are seen sometimes on the same side, and at other times on opposite sides of the planet. These small stars occasionally pass between us and Jupiter, and then they are found to project shadows which are seen to traverse his disc. On the other hand, they are often immersed in the shadow of Jupiter, and exhibit the phenomenon called an *eclipse*. The planets Saturn and Uranus are also similarly attended, the former by seven, and the latter by six, little stars. These accompanying stars are called satellites, and also *secondary planets*, in contradistinction to the others, which are called *primary*.

243. *Saturn* is distinguished from all the other planets, in being surrounded by a circular ring concentric with itself. When first examined by the telescope, this planet was almost always seen between two small luminous bodies of an irregular form, which seemed to be attached to it, and which, as they suggested the idea of handles, were denominated *ansæ*. Sometimes the *ansæ* disappeared, and then Saturn appeared round like the other planets. By tracing with care these singular appearances, and combining them with the positions of Saturn relatively to the sun and the earth, Huygens at last discovered that they are produced by a ring which encompasses the body of the planet, and which is every where separated from it. Being seen obliquely, the ring appears of an oval or elliptic form. Before the time of Herschel the ring of Saturn was supposed to be single; but this distinguished astronomer discovered that it is double: so that two rings concentric, and in the same plane, constitute what was formerly supposed to be a single ring. The ring, which is very thin, is inclined to the plane of the ecliptic. It revolves from west to east in $10^h 39' 54''$. Its breadth is nearly equal to its distance from Saturn; that is, about one third of the diameter of the planet. The interval between the rings is very little; yet Dr. Herschel saw a star through it. The inner ring is somewhat broader than the outer.

CHAP. III.

APPROXIMATION TO THE FIGURE AND MAGNITUDE OF THE EARTH.

244. *The true figure and exact magnitude of the earth* are elements of the highest importance in geography. Their determination, however, has required the aid of astronomy in its most improved state; yet it is necessary, to the explanation of the general doctrines of astronomy, that we should, in the outset, know nearly its figure and magnitude: we shall afterwards explain by what means the first conceptions have been corrected, and its true figure and magnitude found. Having now pointed out, generally, the phenomena of the heavens — taking into view the more remarkable discoveries made by aid of the telescope — we are next to consider *the causes and mutual dependence of these phenomena*. The first step towards obtaining an explication of the motions of the heavenly bodies, is to form some notion of the figure and magnitude of the earth which we inhabit, and from which all the celestial phenomena are observed. To a person placed in an elevated situation in an open country, where the view is unconfined on all sides, the earth appears an extended plane, with the concave sphere of the heavens resting upon it, — the horizon being the common boundary. This appearance is, however, altogether illusory.

245. *The earth is a round body*, and is isolated in space. This is sufficiently established by the following facts: —

1. To an observer who travels from north to south the nocturnal heavens appear continually to change their aspect. The stars, indeed, retain the same relative position in respect of each other, and the points on which the heavens appear to revolve remain unchanged; but the angle, which the axis of their motion forms with the horizon, continually decreases; so that stars which, at the place from which he set out, appeared to reach their greatest elevation to the south of the point directly over his head, now that he has changed his position,

appear, when highest, on the north of that point. This clearly indicates that his path on the earth's surface has not been a straight line, but a curve of which the convexity is turned towards the sky.

2. The convexity of the earth is quite apparent to a spectator in a ship receding from the shore. At first low objects disappear; then those more elevated; and at last the highest points of the land sink in the horizon, on account of the direct visual ray being broken by the interposed curved surface of the ocean. In like manner, when two ships approach each other, the navigators in each see at first the upper part of the rigging of the other vessel, the hull being still invisible: as the distance becomes less the body of each vessel comes gradually into view. The reverse happens if the distance between the vessels is increasing. From these appearances it is evident, that a straight line joining any two points of the earth's surfaces passes within the body of the earth.

3. That the horizon of the sea, which, to the eye, terminates its surface, is only an apparent limit in reference to the position of the observer, is evident from the fact, that if we advance towards it we find it recede; and, at the same time, we still imagine ourselves placed in the centre of an extended plane, bounded by the line in which the heavens and earth appear to meet. This is what the navigator uniformly experiences; while, to an observer on the shore, his vessel appears to sink below the horizon; and by continuing to sail in the same direction, he will at last arrive at the same port from which he set out, — having thus circumnavigated the earth. This enterprise has, it is well known, in numerous instances, been accomplished by navigators, who have left the shores of Europe and returned home, some by sailing always towards the west, and others by holding an easterly course. This great experiment demonstrates that the sea and land have a curved surface which returns into itself, so that no part of it is touched by the heavens.

246. *There are other phenomena which prove that the earth, if not an exact sphere, is at least nearly of that figure.* The various appearances of the moon, in the course of her revolution round the earth, show that she is an opaque body, and is visible only by the reflected light of the sun. The earth being also an opaque body, must project a shadow in a direction opposite to the sun. It will afterwards be shown that the moon, when full, must sometimes pass through this shadow. In this case, when the moon begins to penetrate, or is about to leave, the shadow, the greater part of the disc is still illuminated by the sun; and it is found that this luminous part is always of the form of a crescent, having its concave side bounded by an arch of a circle. The section of the earth's shadow, shown by its projection on the moon, is, therefore, as to sense, circular, — a proof that the earth is a sphere, or nearly of a spherical figure; whence we may conclude that there is a point within the earth which is its centre.

247. *That the earth is a round body, is thus completely proved by experience and observation;* yet, when this doctrine is presented to the mind for the first time, there is some difficulty in believing that the earth is balanced, as it were, on its centre, without any visible support; while all things at rest on its surface require to be supported. We must, however, consider that the bodies which we see fall towards the centre of the earth are mere atoms in comparison to the earth itself; and that, although their tendency to its centre is another fact established by experience, yet it does not thence follow that the earth itself should move towards one point of space rather than towards another. A little reflection will show that there is no inconsistency in supposing the earth, an immense mass, to be at rest, and all things to be retained on its surface by some force analogous to that by which a piece of iron is drawn towards a magnet. This is really the fact; and a consequence of it is, that on opposite sides of the earth its inhabitants stand in opposite directions, with their feet towards each other, for which reason they are called *Antipodes*; and every country has its own *Antipodes*.

248. *The knowledge of the true figure and magnitude of the earth is of the greatest importance in geography, and on this account we shall treat of them in a particular manner.* In the mean time, as a near approximation to the truth, the earth may be considered as differing but little from a sphere, 7916 miles in diameter, and consequently nearly 24,870 miles in circumference. In geometry, the circumference of every circle is supposed to be divided into 360 equal parts, called degrees; and each of these into 60 equal parts, called minutes, and so on. A degree, therefore, of any circle on the earth's surface, whose centre is the same with that of the earth, will be rather more than 69 miles; and a minute of a degree will be about $1\frac{3}{40}$ mile.

CHAP. IV.

DOCTRINE OF THE SPHERE.

249. *The motions of the celestial bodies being in appearance all performed on a sphere, of which the eye of the spectator is the centre; with a view to describe the nature of these mo-*

tions, it has been found expedient to suppose certain circles to be traced on this sphere, to which, also, the positions of the heavenly bodies in space are referred.

250. *The distance of the fixed stars* is immensely great in respect of the earth's semidiameter: for it is found that, when viewed from any two points of the earth's surface, they have the very same relative position, and the same apparent distances, at a given instant of time. Hence it follows, that the appearance of the heavens, and the angular distances of the fixed stars, will be, as to sense, the same, whether they be viewed from the centre of the earth, or from a point on its surface. We may, therefore, conceive the axis of the diurnal revolution to pass through the centre of the earth, which will be also the centre of the celestial sphere.

DEFINITIONS.

251. *A great circle* of the sphere is that whose plane passes through its centre: and all others are called small circles.

252. *A circle of the celestial sphere*, whose plane passes through the earth's centre, and is perpendicular to the axis, is called the *EQUATOR*. The line in which this plane meets the earth's surface is called the *EQUATOR* of the earth, or the *EQUINOCTIAL*.

253. *To illustrate this by a diagram*, let *c* be the centre of the sphere (*fig. 15.*), which

we suppose to coincide with the centre of the earth, and let *P c p* be the axis; then the circle, whose diameter is *E Q*, which passes through *c*, and is perpendicular to *P p*, is the *Equator*. The circles which the stars describe by the diurnal revolution, are all parallel to the Equator. Such is the circle whose diameter is *A B*.

254. *A circle*, whose plane passes through the poles, is called the *MERIDIAN*, and the section of the earth's surface made by this plane is called the *MERIDIAN* of all the places through which it passes. Thus *P E p Q* is a meridian circle in the heavens. The number of these circles is indefinite.

255. *By the geometrical properties of a sphere*, the plane of any meridian cuts the planes of the equator and all circles parallel to it at right angles.

256. *We know by observation*, that any body at rest, and let fall from a point above the earth, will, by its weight or gravity, descend in a straight line. This line is the *direction of gravity*: it is also indicated by the direction of a cord to which a plummet is suspended, and is every where perpendicular to the surface of water at rest. If, now, a line in the direction of gravity at any point on the earth's surface be produced indefinitely upward and downward, this line, called a *VERTICAL*, will mark, on the celestial sphere, two points called the *ZENITH* and *NADIR*. The former is the point in the heavens immediately over head. A plane conceived to pass through any place on the earth's surface at right angles to the line joining its zenith and nadir, will, when extended to the heavens, meet the sphere in a circle, which is the *HORIZON* of that place. A plane that passes through the earth's centre, and is parallel to the plane just now defined, will meet the sphere in a circle, which is also called the *HORIZON*; but, to distinguish the one from the other, the former is called the *SENSIBLE*, and the latter the *RATIONAL HORIZON*. On account, however, of the smallness of the earth's semidiameter, when compared with the immense distances of the fixed stars, the two horizons are, as to sense, the same.

257. The zenith is at *Z* (*fig. 15.*), and nadir at *N*. The circle *H O R* is the horizon.

258. *If the earth were a perfect sphere*, the direction of gravity being every where perpendicular to its surface, all bodies would tend towards its centre. But if there be *any deviation from the exact spherical figure*, (and this is really the case,) then the direction of gravity will not, in general, pass through the centre; though, if the deviation be small, it will nearly pass through that point.

259. *The plane of the horizon* of any place touches the earth's surface, and divides the whole expanse of the heavens into two *HEMISPHERES*; one of which, *viz.* that above the horizon, is *VISIBLE*, and the other *INVISIBLE*. To an eye placed close to the earth's surface, or to the surface of the sea, the two hemispheres will appear exactly equal. A spectator, however, on the top of a mountain, can see more than half of the heavens; because, if a line drawn from his eye to touch the earth's surface were carried round, it would generate the surface of a cone. The portion of the heavens within this cone would be invisible; but he would see all the space without the cone, which would manifestly be the larger portion.

His apparent horizon would still be a circle ; but it would be below the plane passing through his eye perpendicular to the vertical. The depression of the horizon of a spectator so situated below this plane is called the *Dip*.

260. *Circles whose planes pass through the zenith and nadir of any place* are called **VERTICAL CIRCLES**. Such, for example, is the circle *Z O N*. These, by the properties of a sphere, are all perpendicular to the horizon. The meridian is, of course, a vertical circle ; and the vertical circle whose plane is perpendicular to the meridian is called the **PRIME VERTICAL**.

261. *The meridian cuts the horizon in the North and South points, and the prime vertical cuts it in the East and West.* These four are the **CARDINAL POINTS**. They divide the horizon into four equal parts.

262. *Let a vertical circle be supposed to pass continually through a star, or any point of the heavens, the arc of that circle between the star and the horizon is called the ALTITUDE of the star ; and the arc of the horizon between the vertical circle and the meridian is called its AZIMUTH, which may be measured either from the north or south.* Thus, in *fig. 15.*, suppose a star at *S*, then its altitude is the arc *S O*, and its azimuth the arc *H O*.

263. *Vertical circles are called CIRCLES of AZIMUTH.*

264. *The altitude of a star will evidently be greatest when it is on the meridian, and it will have equal altitudes when it is at equal distances from the meridian ; that is, when its eastern and western azimuths are equal.*

265. *Suppose a meridian to pass through a star, then the arc intercepted between the star and the equator is called the DECLINATION of the star.* Thus *P S p* being a meridian that passes through the star *S*, and meets the equator in *K*, the arc *S K* is the declination of the star.

266. *If a meridian circle pass through the zenith of any place, the arc intercepted between the zenith and the equator is called the LATITUDE of that place.* Thus *Z* being the zenith of any place, and *E K Q* the equator, the latitude of the place is the arc *ZE*.

267. *Assuming the meridian circle that passes through the zenith of any particular place as the FIRST MERIDIAN, the arc of the equator intercepted between the first meridian and the meridian circle passing through the zenith of any other place, is called the LONGITUDE of that place.* It is usual, in this country, to reckon the longitude of places from the meridian circle that passes through the zenith of the Observatory at Greenwich.

268. *Because the arcs ZR, the distance of the zenith from the horizon, and PE, the distance of the pole from the equator, are each one fourth of the circumference of a circle or a quadrant, they are equal, and consequently, leaving out the common arc PZ, the arcs ZE and PR are equal.* Hence it appears that *PR*, the distance of the pole from the horizon of any place, called the *elevation* or *altitude* of the pole, is equal to the latitude of that place.

CHAP. V.

ROTATION OF THE SUN, MOON, AND PLANETS ON THEIR AXES. THEIR FIGURE.

269. From the phenomena of the spots which, by aid of the telescope, are visible on his disc, we are led to conclude that *the sun revolves from west to east, on an axis, in about twenty-five days and a half.* Though these spots are subject to many variations, they are sufficiently permanent to enable us to discover that they have regular motions across the disc, exactly the same as must belong to corresponding points on the surface of the sun, supposing him actually to have a motion of rotation from west to east on an axis nearly perpendicular to the plane of the **PATH OR ORBIT**, which, in virtue of his apparent motion, he describes round the heavens in the course of a year. When a spot is first discovered on the eastern edge of the disc, it appears like a fine line : as it approaches the centre of the disc its breadth increases : as it advances towards the western edge the breadth again diminishes, until the spot at length entirely disappears. The same spot is sometimes again observed, after fourteen days, on the east side of the disc ; but more frequently the spot is dissolved, and is no more seen. By careful observation of the time occupied by a spot in crossing the disc, taking also into account the proper motion of the sun from west to east during that period, the time of the sun's rotation on his axis is found to be about twenty-five and a half days.

270. *That the moon, and the planets Mercury, Venus, Mars, Jupiter, and Saturn, have each a motion of rotation from west to east, on an axis inclined to the plane of the sun's orbit, is inferred in like manner from the spots that are seen to traverse their discs.* The moon presents always nearly the same side to the earth ; and must, therefore, revolve on her axis in the same time in which she is carried round the heavens by her apparent motion, namely, in $27^d 7^m 43^s$. Mercury revolves in $24^h 5^m$; Venus in $23^h 30^m$; Mars in $24^h 39^m$; Jupiter in $9^h 56^m$; Saturn in $10^h 29^m$. In the remaining planets no appearances have

been discovered which enable us to ascertain whether or not they revolve on axes: though, from analogy, it is highly probable that they do.

271. *With regard to the figure of the sun and of those planets which are known to revolve on axes*, we may conclude that they are nearly spherical; because no other but a spherical body can, when revolving on an axis in the manner of the planets (with the exception of the moon), present in every position the appearance of a circular disc. The spherical figure of the moon, and, indeed, of the other planets which exhibit phases, may be inferred from the fact, that the concavity of the crescent which they from time to time display is bounded by an elliptic line. The planet Uranus always presents a disc that is nearly circular, and it has not been ascertained that he revolves on an axis; but it is very improbable, when we consider how very irregular his motions among the fixed stars appear when seen from the earth, that he should keep the same side always turned towards us. His apparent motion is sometimes direct, that is from west to east, sometimes retrograde, or in the contrary direction; so that to present constantly the appearance of a circular disc, the planet would require, were it not spherical, to have motions in opposite directions about the same axis. The same reasoning will apply to the remaining planets. We may conclude, therefore, that the sun, moon, and planets, are bodies nearly spherical.

CHAP. VI.

DISTANCES AND MAGNITUDES OF THE HEAVENLY BODIES.

272. *Distances of the fixed stars.* From whatever point of the earth's surface we observe the fixed stars, they always appear to preserve the very same relative positions. We may hence conclude that these bodies are situated at immeasurable distances from the earth; and that though to us who inhabit it the dimensions of the earth appear very great, they are insensible when compared with these immense distances. The earth is in reality but as a point in space. But though the fixed stars are vastly too remote to admit of their distances being determined, we have reason to believe that they are placed at very different degrees of remoteness. They shine with very various degrees of brilliancy; multitudes are not visible without the aid of the telescope, and it may reasonably be supposed that many more have not yet been discovered by the most powerful instruments which have been directed to the heavens.

273. *The distances of the fixed stars* being unknown, we can only form conjectures from hypothesis and analogy respecting their true magnitudes. When viewed through the best telescopes, they have no apparent diameter, but appear like points in the heavens.

274. *Mode of determining the distance of the sun, moon, and planets.* In reference to the sphere of the fixed stars, then, the earth is to be regarded as a point. To a spectator, at the sun, moon, and planets, however, it would present a disc subtending an angle of greater or less magnitude, and, even when smallest, admitting of measurement. This angle can be determined by an observer on the earth's surface; and as we know the true magnitude of the earth, it affords us the means of estimating the distances of these bodies. Let Oo be the

places of two observers under the same meridian, but very distant from each other. Let P be a planet in the meridian of these places, and let some fixed star which comes to the meridian at the same time with the planet, be seen by the observers at O and o , in the directions OS , os . Join OP , oP , and produce OP , to meet os in A . Then, because OS , os are parallel (the distance of the star S being regarded as infinite), the angles OAO , AOS are equal: and, because OPo is the exterior angle of the triangle oAP , it is equal to the sum of the two interior and opposite angles AOP , oAP . Wherefore the angle OPo is equal to the sum of the angles AOP , POS : that is, the angle subtended at the star by the chord of the terrestrial arc intercepted between the points of observation, is equal to the sum of the apparent distances of the planet from the star, provided the planet is seen (as we have here

supposed) on opposite sides of the star by the two observers. If the star is seen on the same side by both, the angle at the planet will then be equal to the difference of the apparent distances.

275. If the observers are so situated that PO , Po are tangents to the circle OEO at the points O and o , the angle OPo will be the angle subtended by the disc of the earth at the planet. But if PO , Po are not tangents, draw PO' and Po' tangents to the circle OEO , and from C the centre draw CO' , Co' to the points of contact: draw also the vertical lines CZ and CZ' through O and o the places of the observers, and produce PO , Po to meet CO' , Co' in B and D . Now, for the sun and planets the angle OPo is very small, and even for the moon it is not very considerable. The distance PC may therefore be regarded, in every case, as much greater than CO' , or Co' . Hence the lines CO' , CB , CD may without sensible error be considered as proportional to the angles CPO' , CPB , CPD ; so that we have $\angle CPO' : \angle CPO = CO' : CB$ and $\angle CPO' : \angle CPo = CO' : CD$; wherefore $\angle CPO' : \angle CPO + \angle CPo$ or $\angle OPo = CO' : CB + CD$. But the angles at B and D are very nearly right angles, and therefore, to radius CO' , we have $CB = \text{Sin. } COB = \text{Sin. } POZ$; and $CD = \text{Sin. } CoD = \text{Sin. } PoZ'$: Hence we obtain $\angle CPO' : \angle OPo = (CO : CB + CD) = \text{Rad.} : \text{Sin. } POZ + \text{Sin. } PoZ'$: And $2 \angle CPO'$ or $\angle O'Po' = 2 \angle OPo \times$
Rad.

$\text{Sin. } POZ + \text{Sin. } PoZ'$

276. If the planet be on the same side of the zenith to both observers, then the difference, instead of the sum of the sines of the zenith distances, must be taken for the denominator. Expressing the above formula in words, we give the following simple rule:— *Divide the arc, (expressed in parts of the radius,) which measures the observed angle at the planet, by the sum of the sines of the zenith distances of the planet, if it is between the zeniths of the two observers; or by the difference of these sines if the planet is on the same side of the zenith to both observers; and twice the result will be the arc, expressed in parts of the radius, that measures the angle subtended at the planet by the disc of the earth.*

277. Since small angles, that require for their measurement only the use of the micrometer, can be determined with much more accuracy than large angles requiring the whole telescope to be moved, it is best to employ, in finding the angle OPo a star which is near the planet: a small error in taking the zenith distances of the planet will produce no sensible error in the result.

278. Another method of determining this angle, is by observations on the transit of Venus over the disc of the sun; a phenomenon in which the planet is seen like a dark spot on the disc; but the method now explained is sufficient for our present purpose.

279. The following are the angles subtended by the earth's disc at the sun, moon, and planets, when the earth is nearest to each:

Angle at the Sun	Seconds.
	= 17
Mercury	= 28
Venus	= 62
Mars	= 42
Jupiter	= 4
Saturn	= 2

Angle at Uranus	Seconds.
	= 1
Vesta	} = 9
Juno	
Ceres	
Pallas	
Moon	= 2' 2"

280. To determine, now, the distance of the sun or moon, or of a planet:— In the right angled triangle POC we have given the angle P equal to half the angle subtended by the earth's disc at the body whose distance is to be found; also OC the earth's semi-diameter: therefore the distance PC may be determined by the proportion $\text{Sin. } P : \text{Rad.} = CO : PC$. Since the angle P is small, its sine must be nearly equal to the arc which measures it. Observing therefore that the arc to which the radius is equal, expressed in seconds, is 206265" we have $\angle P$ (in seconds) : 206265 = $CO : PC$.

Hence $PC = 2CO \times \frac{206265}{2P}$. Whence we derive the following rule:— *Divide the constant number 206265 by the number of seconds in the angle subtended by the earth's disc as seen from the body whose distance is to be determined; multiply the result by the diameter of the earth, and the product is the distance required.*

In the case of the sun; assuming the diameter of the earth as unity, we have the distance equal to $\frac{206265}{17}$ or 12133 diameters of the earth. In like manner, taking 4", 2", 1" for the angles subtended by the earth's disc at Jupiter, Saturn, and Uranus, the distances of these planets from the earth, when least, will be 51566, 103132, 206265 diameters of the earth respectively. The mean distance of the moon is about sixty semi-diameters of the earth.

281. The apparent diameter of any one of the heavenly bodies, is the number of seconds in the measure of the angle under which its circular disc is seen by a spectator upon the earth. When measured by a micrometer, the apparent diameters of the sun, moon, and planets are found to be, when greatest, as follow:

Diameter of the Sun	Seconds.
	= 1923
Mercury	= 12
Venus	= 61
Mars	= 18

Diameter of Jupiter	Seconds.
	= 46
Saturn	= 18
Uranus	= 4
Moon	= 2020

The four remaining planets, according to the most careful observations, appear to subtend only a small part of a second.

282. Now, for deducing the real diameters from the apparent, we have this rule: — *As the apparent diameter of the earth, (or the seconds in the angle which its disc subtends,) as seen from the planet, is to the apparent diameter of the planet as seen from the earth, so is the true diameter of the earth to the true diameter of the planet.*

283. Calling the diameter of the earth unity, or 8000 miles in round numbers, we obtain,

	Diameters of the Earth.	Miles.
Diameter of the Sun	= 111.454	= 882,000 nearly.
Mercury	= 0.398	= 3,140 —
Venus	= 0.9	= 7,200 —
Mars	= 0.517	= 4,100 —
Jupiter	= 10.860	= 90,000 —
Saturn	= 9.982	= 76,068 —
Uranus	= 4.332	= 34,500 —
Moon	= 0.273	= 2,160 —

284. *As the sun, moon, and planets are spherical bodies, their magnitudes compared with the magnitude of the earth, may be found upon the principle that similar solids are to one another as the cubes of their similar dimensions; so that as the cube of the diameter of the earth is to the cube of the diameter of the sun, moon, or a planet, so is the magnitude of the former to the magnitude of the latter.*

285. Assuming the magnitude of the earth as unity :

The magnitude of the Sun	= 1384472.000
Mercury	= .063
Venus	= .927
Mars	= .139
Jupiter	= 1280.900
Saturn	= 995.000
Uranus	= 80.490
Moon	= .020

Having now ascertained the distances and magnitudes of the heavenly bodies, we proceed to enquire whether the diurnal motion which we observe in them be a real or only an apparent motion; and whether the earth is the centre to which the proper motion of any of them is to be referred.

CHAP. VII.

ROTATION OF THE EARTH.

286. *The diurnal motion of the heavenly bodies suggests the existence of some cause, under the influence of which they either perform or appear to perform a revolution from east to west round the axis of the celestial sphere in the space of a day and a night. Now, there are two suppositions, on either of which the diurnal motion may be explained. We may suppose the heavens to be carried round the earth, while the latter remains immoveable in the centre; or we may suppose the heavens to be at rest, and the earth to revolve on an axis in an opposite direction; that is, from west to east. To which of these hypotheses the preference is due, will be evident if we consider that the heavenly bodies are independent one of another, and are placed at very different distances from the earth; that variations in the apparent diameters of the planets indicate great changes in their distances, while the comets traverse the heavens in all directions; so that it is difficult to conceive that one and the same cause should impress on all these bodies a common motion of rotation.*

287. *Since the earth is a globe of about 8000 miles diameter, it is small when compared with the immense mass of the sun. Were the centres of the sun and earth brought into coincidence, the former body would fill the orbit of the moon and extend as far again beyond it. Besides, the sun is distant from us about twelve thousand diameters of the earth; so that to revolve round the heavens in the interval of twenty four hours, he must move at the immense velocity of about twenty five millions of miles in an hour. It is therefore more reasonable to suppose the earth to have a motion of rotation on an axis, than to suppose the sun, a body so distant and of such immense magnitude, to move with the vast rapidity that would be requisite to carry him round the heavens in so short an interval. With regard to the fixed stars, we may reason in the same manner with still greater force: for the velocity necessary to carry the sun round in twenty-four hours is really insensible when compared with the rapidity with which the fixed stars must move to accomplish a like*

revolution. In order to account for the diurnal motion of the heavens on the hypothesis that the earth is at rest, it must be supposed that the sun, moon, and stars have their velocities so adapted to their respective distances, that all of them complete their revolutions round the earth in exactly the same number of seconds. Such an adaptation among innumerable independent bodies, placed at such a variety of distances, it is impossible to admit.

288. *There are other phenomena of the heavens which serve still farther to confirm the conclusion, that the diurnal motion of the heavenly bodies is not a real motion.* Every difficulty, however, disappears, if we suppose the earth to have a motion of rotation on an axis from west to east. Carried round with a velocity common to all the objects which surround us on the earth's surface, we are in a situation similar to that of a spectator placed in a vessel in motion. At the first careless glance he imagines himself at rest, while the shore, and all the objects which he sees, unconnected with the vessel, appear to be in motion. By reflecting, however, on the extent of the shore, on the magnitude of the mountains, and other objects on land, when compared with the vessel from which he observes them, he frees his mind from this momentary illusion, and becomes convinced that the motion of these objects is only apparent, and that it is produced by the real motion of the vessel. The multitude of stars scattered over the heavens are, with respect to us, what the shore and the objects upon it are with regard to the spectator placed in the vessel: and by the same considerations, by which his first impressions are so corrected that he becomes assured of the reality of his motion, we are led to the conclusion that the rotation of the earth on an axis produces the apparent diurnal motion of the heavens.

289. *An argument for the rotation of the earth may also be drawn from analogy.* Several of the planets are known to have a motion on an axis similar to that which we have supposed to belong to the earth. Jupiter, for example, which is many times greater than the earth, revolves on his axis from west to east in less than half a day; and to an observer on his surface, the heavens would appear to revolve round that planet in the same manner as we see them revolve round the earth, but in about half the time. This motion of the heavens in reference to a spectator on the planet Jupiter would, however, be only apparent; and hence we may reasonably conclude, that the case is the same in reference to a spectator on the earth.

290. Lastly, if the earth is actually in motion, there will be generated a *centrifugal force*, or a tendency to throw off objects from its surface, which must diminish the force of gravity, particularly at the equator, where the motion is most rapid. Now, by observations made with the pendulum, this diminution of the force of gravity has been found to exist. The same cause affects also the figure of the earth, which has been found to be flattened somewhat at the points of rotation, and elevated at the equatorial regions. The same is observed to be the figure of Jupiter, — a circumstance which greatly strengthens the argument drawn from analogy. The evidence which has now been adduced leaves no doubt respecting the earth's motion of rotation; and thus we are enabled to ascertain the true place which the globe that we inhabit holds in the universe.

291. *The points in which the axis of rotation meets the surface are called the POLES of the earth; and it is evident that the axis, if produced, must pass through the poles of the heavens.*

CHAP. VIII.

APPARENT ANNUAL MOTION OF THE SUN. VICISSITUDE OF SEASONS.

292. *While the sun participates in the diurnal motion of the heavens, he also appears to move eastward among the fixed stars.* This motion it will be of importance now to trace out, and to explain the change of seasons to which it gives rise. If we observe each day of the year the meridian altitude of the sun, and note the time which elapses between his passage over the meridian and the passage of any particular star, we shall have the apparent motion of the sun in the direction of the meridian, and of the circles parallel to the equator in which he appears daily to be carried by the diurnal motion of the heavens. The result of the composition of these two motions will give the true motion for each day. In this manner it has been found that the sun moves in a path or orbit which cuts the equator in two opposite points, and makes with it an angle equal to $23^{\circ} 28'$ nearly.

293. *The name of ecliptic is given to the circle which the plane of this orbit marks out on the sphere of the heavens.* It passes through twelve constellations, which are called the *TWELVE SIGNS*. This has given rise to the division of the ecliptic into twelve equal parts, called *SIGNS*, each containing, of course, 30° . The twelve signs are contained in a zone of the starry heavens, called the *ZODIAC*. The names of these constellations, with the characters by which they are usually denoted, are as follow: — Aries γ , Taurus β , Gemini Π ,

Cancer ☉, Leo ♌, Virgo ♍, Libra ♎, Scorpio ♏, Sagittarius ♐, Capricornus ♑, Aquarius ♒, Pisces ♓.

294. *The vicissitude of seasons* arises from the combination of the apparent motion of the sun in the ecliptic with his apparent diurnal motion. When the sun is in either of the points in which the ecliptic intersects the equator, he describes the equator on that day in virtue of his diurnal motion; and as by the properties of the sphere this circle is divided into two equal parts by the horizon, at whatever point of the earth's surface the spectator is situated, the day is then equal to the night over all the globe.

295. *The points of intersection of equator and ecliptic* are called the EQUINOCTIAL POINTS. The first point of the sign *Aries* is supposed to coincide with the point of the vernal equinox; and from that point the signs of the ecliptic are reckoned: the first point of the sign *Libra* will therefore coincide with the point of the autumnal equinox. As the sun, when he leaves the point of the vernal equinox advances in the ecliptic, his meridian altitude above our horizon daily increases, and a larger portion of the parallel which he daily describes becomes visible. Hence arises a gradual increase in the length of the day in all countries to the north of the equator; until the sun having reached his greatest altitude, the day acquires its greatest length, and begins to shorten. As the variations of the altitude on each side of the points at which it is greatest are insensible, the sun, if we attend only to his altitude, appears stationary, and the day continues, for some time, very nearly of the same length. The point of the ecliptic at which the *maximum* takes place is therefore denominated the point of the SUMMER SOLSTICE. The sun, having reached this point, now returns towards the equator, which he crosses at the point of the autumnal equinox. His meridian altitude gradually diminishes until it reaches the *minimum* at the point of the WINTER SOLSTICE. The day, which has been gradually shortening from the summer solstice, is then the shortest in the year, and for some time does not sensibly lengthen. The sun, however, again gradually approaches the equator, and reaches it at the vernal equinox.

296. Such is the *constant progress of the sun in the heavens, and such the succession of the seasons* of the year. The SPRING is the time comprised between the vernal or spring equinox, which falls about the 21st of March, and the summer solstice, which happens about the 21st of June: the interval between the solstice and the autumnal equinox, which falls about the 23d of September is the SUMMER: the time between the autumnal equinox and the winter solstice, which occurs about the 22d of December, is the AUTUMN: and, lastly, the WINTER is the time that elapses between the winter solstice and the spring equinox.

297. *The two circles parallel to the equator*, which the sun describes on the longest and shortest days, are called, one the summer or northern TROPIC, and the other the winter or southern TROPIC. They are also respectively denominated the tropic of Cancer and the tropic of Capricorn, in reference to the points in which they touch the ecliptic.

298. *The presence of the sun above the horizon being the cause of heat*, and the temperature increasing as the altitude increases, it might be inferred that the temperature should be the same in summer as in spring, and in winter as in autumn; because the altitudes of the sun in these seasons exactly correspond. But it is to be observed that the temperature is not an instantaneous effect of the sun's presence; but is the result of the continued action of his rays. On this account it is not greatest on the day when the altitude is greatest, but some time between the summer solstice and autumnal equinox. In like manner, the greatest cold of winter does not occur on the shortest day, but some time between the winter solstice and the spring equinox.

299. *With regard both to temperature and the length of the day*, great differences arise from the different elevations of the pole above the horizon, as we proceed from the equator towards either of the poles. The horizon of an observer at the equator passes through the poles, and by the geometrical properties of the sphere it divides the equator and all the circles parallel to it into two equal parts. It also cuts them at right angles; and hence the position of the celestial sphere, in reference to the horizon of an observer at the equator, is called the RIGHT position of the sphere. In whatever point of the ecliptic the sun is situated, his diurnal course is therefore at right angles to the horizon, and one half of it is in the visible hemisphere, and the other half in the invisible; hence, at the equator, the day is at all seasons equal to the night.

300. *When the sun is in either of the equinoctial points*, he passes through the zenith at mid-day. When he is in either of the solstitial points his meridian altitude is the least, and is equal to the complement of the inclination of the ecliptic to the equator. In these two positions of the sun the shadows of objects fall, at mid-day, in opposite directions, — a phenomenon which at no season occurs in our climate, where the solar shadows are at mid-day always directed towards the north: there are, then, properly speaking, two summers and two winters in the year at the equator. The same thing takes place in all the countries where the elevation of the pole above the horizon is less than the obliquity of the ecliptic. In every country beyond this region there is only one summer and one winter in the year, with the intervening seasons of spring and autumn: the sun is never in the zenith: the length of the longest day increases, and that of the shortest day diminishes, as we advance

towards either of the poles; and when we have reached such a position, that the zenith is distant from the pole by an arc of the meridian equal to the obliquity of the ecliptic, the sun does not set at the summer solstice, nor rise at the winter solstice.

301. *The polar circles.* About each of the poles of the celestial sphere, suppose a circle to be described distant from it by an arc equal to the obliquity of the ecliptic; these two circles are called the **POLAR CIRCLES**. In the region of the earth situated around either of its poles, at every point whose zenith lies within the polar circle, the time of the sun's presence above the horizon and of his absence below it, at certain seasons, exceeds twenty-four hours: it increases as we approach the pole, and may amount to days or even to months. Thus, when the sun's declination north, increasing, becomes equal to the distance of the zenith of any place in the northern polar region from the north pole of the heavens, he ceases to set at that place, and continues above the horizon until he has reached the same declination in returning towards the equator. From that time the sun rises and sets in the course of twenty-four hours, until the sun's declination south becomes equal to the distance of the zenith from the pole, and then he ceases to rise and continues below the horizon till he has again acquired the same declination in returning northward.

302. *At the pole, the equator coincides with the horizon, and all the circles parallel to the equator are also parallel to the horizon.* This is called the **PARALLEL** position of the sphere. To an observer, placed at the pole, the heavenly bodies would appear to move round, either in the horizon or parallel to it. Hence the sun is constantly above the horizon when he is on the same side of the equator with the pole, and constantly below it when on the other side; so that at either of the poles of the earth there is only one day and one night in the year.

303. *At any point on the earth's surface, between the equator and either of the poles, the equator and the circles parallel to it are oblique to the horizon.* This is called the **OBLIQUE** position of the sphere; and by the geometrical properties of the sphere, the horizon, in this position, divides all the circles parallel to the equator into two unequal parts; hence arises the inequality of the days and nights at all places between the equator and either pole. In this country, for example, in summer, when the sun is on the north side of the equator, the larger portion of his diurnal course lies in the visible hemisphere, and the less in the invisible, so that the day is longer than the night. The reverse is the case in the winter when the sun is on the south side of the equator.

304. *If two places are situated on opposite sides of the equator, the spring and summer of the one will, it is evident, correspond to the autumn and winter of the other.*

305. *With regard to the temperature, it is higher in the equatorial regions than in any other part of the earth, because there the action of the sun's rays is most direct.* To every point of the earth's surface, whose zenith lies between the tropics, the sun is vertical twice in the year; so that his rays, acting perpendicularly, produce their greatest effect. In the polar regions the temperature is lowest, in consequence of the obliquity with which the sun's rays fall on the earth's surface, and the great length of the winter night. In the countries situated between the equatorial region and the two polar regions, there prevails a medium temperature, increasing as the zenith approaches the nearer of the two tropics, and diminishing as it approaches the nearer of the polar circles.

306. *A division of the earth's surface into five zones has been suggested by this difference of*

temperature from the equator towards either pole. In the adjoining figure let Pp represent the earth's axis, PE, pQ , a meridian, and EQ the equatorial diameter. Let ECQ be the representation of a circle on the earth's surface equally distant from the poles, which will therefore be the *equator*: and FGH, fgh circles on the earth's surface parallel to the equator, and at the distance of about $23\frac{1}{2}$ degrees; on each side of it, and ABD, abd circles round the poles P, p , and at the same distance of $23\frac{1}{2}$ degrees.

307. *At the times of the year when the sun is in the tropics of Cancer, he will, in his apparent revolution, be vertical to all places on the circle FGH ; and when he is in the tropic of Capricorn, he will be vertical to the circle fgh .* The space on the earth's surface between these circles is the **Torrid Zone**.

308. *When the sun is in the southern tropic he will not be seen any where in the space bounded by the circle ABD .* This is, therefore, the northern **Frigid Zone**: and when he is in the northern tropic there is a like tract, bounded by the circle abd , round the south

pole, where he will then be invisible. This is the southern *Frigid Zone*. The two tracts between the torrid zone and the frigid zone are the temperate zones.

309. *Another division of the earth into zones* was used by the ancient geographers, founded on the different lengths of the longest day, as we proceed from the equator towards either of the poles. These zones were denominated *CLIMATES*, and were each of such a breadth, that the longest day at the boundary nearer the pole exceeded the longest day at the boundary nearer the equator by some certain space of time, as half an hour or an hour. Within the polar circle, the climates were supposed of such a breadth as to make the longest day at the opposite sides differ by a month.

310. *The points in which the equator and ecliptic intersect each other* are not immoveable, but appear, with respect to the fixed stars, to recede towards the west at the rate of $50\frac{1}{10}''$ nearly, annually, or about 1° in 72 years. This motion is called the *PRECESSION* of the Equinoxes. When the constellations of the zodiac were first delineated by the ancient astronomers, the middle of the sign *Aries* was at the point of the vernal equinox, from which it is now distant more than 58° towards the east. In consequence of the precession of the equinoxes, the time in which the sun moves from the vernal equinox to the vernal equinox again, is less than the time in which he moves from any star to the same star again; — the point of the vernal equinox moving westward, so as to meet the sun, and thus anticipate the time of his crossing the equator in the preceding year.

311. *The intervals of time which separate the equinoxes or the solstices* are unequal. Almost eight days more elapse from the spring to the autumnal equinox, than from the latter to the former. We may therefore conclude, that the motion of the sun is not uniform. From precise and multiplied observations, it has been ascertained that his motion is most rapid at a point of the ecliptic situated near the winter solstitial point, and slowest at the opposite point towards the summer solstice. At the former point the sun describes daily $1^\circ 1' 10''$, at the latter only $57' 11\frac{1}{2}''$. The distance of the sun from the earth is also variable. This is proved by variations observed in his apparent diameter, which increases and diminishes at the same time with his angular velocity, but not in the same ratio. The angular velocities at any two instants of time are, to one another, as the squares of the apparent diameters.

If v and v' be the angular velocities of the sun, or his daily advances in the ecliptic at any two seasons of the year, and d and d' his apparent diameters at the same time, then $v : v' = d^2 : d'^2$.

312. *To diminish the apparent motion of the sun*, it would be sufficient to suppose that body removed to a greater distance from the earth, without altering his true angular velocity. But if the diminution of his motion depended entirely on this cause, the apparent velocity would diminish in the same ratio with the apparent diameter. Since it diminishes, however, as the square of the diameter, there must necessarily be an actual diminution of the velocity of the sun while he recedes to a greater distance from the earth.

His distance being reciprocally as his apparent diameter, if D and D' be his distances at the two seasons when his diameters are d and d' , we have $v : v' = D'^2 : D^2$; and $vD^2 = v'D'^2$.

Hence it appears, that from the combined effect of the two causes influencing the sun's apparent motions, — namely, the diminution of his velocity and the increase of his distance, — his daily angular motion diminishes as the square of his distance increases; so that the product of the square of the distance by the velocity is a constant quantity.

313. *Let us imagine a straight line to join the centres of the sun and of the earth*. This line is usually called the *RADIUS VECTOR*. It is not difficult to prove that the small sector, or the area which the Radius Vector traces in a day, in consequence of the sun's motion, is proportional to the product of the square of this radius by the sun's daily motion, that is, to vD^2 . This area is therefore constant; and the whole area, described by the Radius Vector, setting out from a fixed radius, increases as the number of days reckoned from the epoch when the sun was at the fixed radius.

Since $vD^2 = v'D'^2$, we have $D' = D\sqrt{\frac{v}{v'}}$. Assuming, therefore, any line whatever for D , and finding, by observation, the sun's angular velocity for every day of the year, the value of D' for each day may be found.

Hence we shall be able to trace a curve line representing the orbit of the sun. This curve is found to be not exactly circular, but a little elongated in the direction of the straight line passing through the centre of the earth, and joining the points in the orbit at which the sun is at his greatest and least distances. The resemblance of this curve to an *ellipse* having given rise to a comparison between them, their identity has been discovered. Hence we conclude, that *the apparent solar orbit is an ellipse having the centre of the earth in one of its foci*.

314. *The solar ellipse* is not much different from a circle; for its excentricity, which, from the geometrical properties of the ellipse, is equal to half the difference of the sun's greatest and least distances from the earth, is a quantity which bears but a very small proportion to the distance of the sun. It appears, from observation, that there is a small diminution of the excentricity, — so small, indeed, as scarcely to be perceptible in a century.

315. *The position of the greater axis of the solar ellipse* is not constantly the same. Its

extremities have an annual motion eastward, in reference to the fixed stars, of about $12''$ in the direction of the sun's motion.

316. *The obliquity of the sun's orbit*, or of the ecliptic to the equator, is also subject to change, and appears to have been continually diminishing from the remotest date of astronomical observation. Its present rate of diminution may be stated at nearly $48''$ in a century.

317. *The apparent elliptic motion of the sun* does not represent, with perfect exactness, the results of modern observation. The great precision now attained in the art of observing has made known to us small inequalities, the laws of which it would have been almost impossible to determine by mere observation. These laws can be investigated only after the physical cause has been discovered upon which the phenomena depend.

CHAP. IX.

DIVISION AND MEASURE OF TIME.

318. *The notion of time* is suggested by the succession of phenomena in the universe. When two events exactly correspond in all their circumstances, they are conceived to occupy equal portions of time. The descent of a heavy body to the earth, for example, from a given height, if repeated under precisely similar circumstances, will in every case be performed in the same interval of time. Suppose then that a number of heavy bodies fall to the ground one after another from the same height, — the descent of the second and of each succeeding body commencing at the instant in which the body that preceded it has reached the ground: the whole time occupied by the fall of these bodies will be divided into equal portions, one of which may be assumed as the measuring unit of time. The vibrations of a pendulum, performed under precisely the same circumstances, are employed for estimating the smaller portions of time: the larger portions are determined by the motions of the sun; from which arise the vicissitude of day and night, and the change of seasons.

319. *The Day*, in civil life, is the time that elapses between the rising and setting of the sun; and the *NIGHT* the time between his setting and rising. The *ASTRONOMICAL* or *SOLAR DAY*, on the other hand, comprehends the whole period of the sun's diurnal revolution, and is reckoned from the time of his passing any particular meridian, to the time of his returning to the same meridian. The pendulum usually employed is of such a length as to divide the mean astronomical day into $24 \times 60 \times 60 = 86400$ equal parts called *seconds*; 60 of these parts make a *minute*; 60 minutes make an *hour*; and 24 hours complete the day.

320. *As the apparent motion of the sun* carries him eastward among the fixed stars, the time that elapses between his passing the meridian, and his returning to it again, is longer than the time that intervenes between two successive passages (called *transits*) of any particular star. This latter period is the exact time of the earth's revolution on its axis, and is called a *SIDEREAL day*: it is about $23^h 56^m 4^s$ in length.

321. The motion of the earth on its axis being perfectly uniform, *the length of the sidereal day* is always the same. This is not, however, the case with respect to the astronomical or solar day, which is affected by the unequable motion of the sun, and by the obliquity of the ecliptic. At the summer solstice, towards which the sun's motion in the ecliptic is slowest, the solar day is more nearly equal to the sidereal day than at the winter solstice, when the sun's motion is quickest.

322. *With regard to the effect of the obliquity of the ecliptic* in reference to the length of the solar day, it is to be observed, that, by the geometrical properties of the sphere, equal portions of any circle, whose plane is perpendicular to the axis of revolution, pass over the meridian in equal times; but if the plane of a circle is oblique to the axis, the arcs that pass over the meridian in equal times are not equal. Hence, if the sun moved uniformly in the equator, the solar day would be always of the same length: but as he moves in the ecliptic, whose plane is oblique to the axis, even if he did proceed with a uniform motion, the equal arcs which he daily described would pass over the meridian in unequal times; so that the solar day would be longer or shorter according to the sun's place in the ecliptic.

323. *The motion of the shadow on a sun-dial* marks out time as measured by the sun's motion in the ecliptic: but if the sun moved uniformly in the equator at such a rate as to complete the annual circuit of the heavens, in the same time as he does by his actual motion in the ecliptic, time measured by his motion would then correspond with that of a well-regulated clock.

324. *The difference between the time shown by the sun-dial, and that shown by the clock, is called the EQUATION OF TIME.* The part of this equation which depends on the obliquity of the ecliptic, vanishes at the equinoxes and at the solstices; because at these seasons the sun comes to the meridian at the same moment as he would do if he moved in the equator.

325. *From the vernal equinox till the summer solstice, and from the autumnal equinox till the winter solstice, the time as shown by the sun-dial is in advance of that indicated by the*

clock ; because then the sun's distance from the first point of *Aries*, and first point of *Libra*, passes sooner over the meridian than the equal arc upon the equator, which the sun would have described had he moved in that circle.

326. *Again*, the hour shown by the sun-dial is behind that shown by the clock, from the summer and winter solstices, till the autumnal and vernal equinoxes ; because at these two seasons the distance of the sun from the first point of *Aries*, and from the first point of *Libra*, requires longer time to pass over the meridian, than the equal arc upon the equator.

327. *The part of the equation of time which arises from the unequable motion of the sun, will vanish when he is at his greatest and least distances from the earth; because he is in these two points of his orbit at the same instants of time as he would be if he moved uniformly with his mean velocity; that is, with a rate of motion by which he would describe equally the ecliptic in the same time in which he describes it by his unequable motion.*

328. *The dial, during the time when the sun is moving from the point of his greatest, to the point of his least distance from the earth, is faster than the clock ; because the sun is then at no instant so far advanced in his orbit, as he would have been if he had been moving uniformly with his mean velocity. The reverse is the case while the sun is moving from the point of his least to that of his greatest distance. Time measured by the dial is called APPARENT time ; that shown by a well-regulated clock is called TRUE time. The effect of the obliquity of the ecliptic, and that of the sun's unequable motion, in rendering the dial faster or slower than the clock, sometimes combine with and at other times counteract each other. The amount of each is given in the two following tables for every fifth day of the year ; and by taking the sum or difference, according as the obliquity of the ecliptic and the sun's unequable motion produce similar or opposite effects, a table may be formed of the equation of time.*

329. *Table showing the Part of the Equation of Time that arises from the Obliquity of the Ecliptic.*

331. *The difference between the apparent and the true time*, is very observable about the season when the day is lengthening or shortening with most rapidity. It is a common remark, that when the day is shortening, the change is more observable in the evening than in the morning; but that the reverse is the case when the day is lengthening. This arises from the clock being before or after the sun. Thus, in the end of October, the dial is upwards of sixteen minutes faster than the clock; so that the time of sun-rise, and the time of sun-set will each, as indicated by the clock, appear earlier by 16 minutes, than as indicated by the motion of the solar shadow. Hence the instant of noon, as shown by the clock, appears not to divide equally the time during which the sun is above the horizon: the time from sun-rise till noon, appears longer than from noon till sun-set. Again, about the middle of February, the dial is about 15 minutes slower than the clock; so that the time of sun-rise and the time of sun-set will each, as indicated by the clock, be later by 15 minutes than as indicated by the dial; and the time from sun-rise till noon, as shown by the clock, will appear shorter than the time from noon till sun-set.

332. As the return of the sun to the meridian marks out the day, so his return to the same equinox marks out *another portion of time* of much importance to be determined with accuracy; namely, *the YEAR*. This period comprehends the seasons which divide it into four parts. Within this period also, the moon goes twelve times through all her phases, which occupy the space of nearly twenty-nine and a half days: hence the year has been divided into twelve months, three of which are allotted to each season. By accurate observation it is found, that the time which elapses between the instant at which the sun passes the vernal equinox, and the period of his return to it, is $365^d 5^h 48^m 48^s$. This period is called the *TROPICAL year*. It is found to be shorter than the interval between two successive returns of the sun to the same star by $20^m 29^s$. This last-mentioned period is called the *SIDEREAL year*, and consists of $365^d 6^h 9^m 11^s$.

333. *In order to make such a distribution of time as is accommodated to the purposes of life*, it is necessary so to adjust the reckoning of the solar revolution to the length of the mean solar day, that the beginning of the year may coincide with the beginning of the day, and the seasons may always recur in the same months. If the solar revolution consisted of an exact number of days, there would be no difficulty; but as it includes a fraction of a day, it is evident that one year cannot be made equal to one revolution, without incurring the inconvenience of making the year commence at a different point of time from the beginning of the day. But though one year cannot be made equal to one revolution, a certain number of years may be made equal to a like number of revolutions.

334. *Julius Cæsar introduced* the first near approximation to accuracy on this subject, in the 45th year before the commencement of the Christian era. The Romans had before that time estimated the year according to the course of the moon, in imitation of the Greeks; dividing it into twelve months, which consisted in all of 354 days; but as an odd number was thought the more fortunate, one day was added which made the year consist of 355 days. To make the lunar year correspond with the course of the sun, on which depends the vicissitude of seasons, an intercalary month was inserted every other year, between the 23d and 24th day of February. The intercalation of this month was left to the discretion of the priests, who, from interested motives, inserted often more or fewer than the proper number of days, so as to make the year longer or shorter, according as it suited their own purposes. This caused the months to be transposed from their stated seasons, the winter months being carried back into autumn, and the autumnal months into summer. When Julius Cæsar became master of the state, he resolved to put an end to this disorder, by abolishing the use of intercalations which had been the source of it; and for that purpose, by the assistance of Sosigenes, a celebrated astronomer of Alexandria, he adjusted the year to the course of the sun, and assigned to the respective months the number of days which they still contain. That matters might proceed with regularity from the beginning of the ensuing January, he made the current year, which was called the last year of *confusion*, consist of fifteen months, or 445 days.

335. *The JULIAN year* is founded upon the supposition that the solar revolution is exactly $365^d 6^h$. For three successive years the six hours are omitted; but in the fourth year an additional day is inserted in the month of February, which makes the four years correspond with four solar revolutions. This fourth year, consisting of 366 days, is called *BISSEXTILE* or *LEAP year*. But as the true length of the solar revolution is not $365^d 6^h$, but only $365^d 5^h 48^m 48^s$, the Julian year is too long by $11^m 12^s$; so that before a new year begins, the sun has passed the point of the ecliptic where the preceding year began. The error thence arising is, however, so small, that it was long before it was observed. The Julian Kalendar was introduced into the church at the time of the Council of Nice, in the year 325 of the Christian era; and the vernal equinox was at that time fixed to the 21st of March. In the year 1582, however, it was found that the vernal equinox fell, not on the 21st of March, but on the 11th of that month; so that the Julian year had fallen about ten days behind the sun. If this erroneous reckoning had been continued, the seasons would have entirely changed their places. *It was therefore resolved to reform the kalendar*, which was

done by *Pope Gregory XIII.*, and the first step was to correct the loss of the ten days, by counting the day after the 4th of October, not the 5th, but the 15th day of the month. The error in the Julian year reckoning, being about eleven minutes yearly, amounts to nearly three days in four centuries. Hence to prevent its accumulation in future, it was agreed to suppress three intercalary days in the course of four hundred years, by considering the last of three successive centuries common, instead of leap years. The years in which the intercalary days are omitted are 1700, 1800, 1900: and, in general, the last year of every century not divisible by four, is reckoned a common year, which in the Julian account is bissextile. The degree of accuracy thus attained is very considerable; for taking the annual error at $11\frac{1}{2}$ minutes, in four centuries, it will amount to 4480 minutes, or to $3^d 2^h 40^m$. Of this error, the fractional part, $2^h 40^m$, is all that remains uncorrected; and this error will require the lapse of 3600 years before it amounts to a day.

336. *Other modes of intercalation.* If the tropical year were $365^d 5^h 49^m 12^s$, the Gregorian intercalation would be perfectly exact. Accurate observation proves, however, that the year is shorter by about 24 seconds. If scientific principles had been strictly followed, they would have pointed out other modes of intercalation still more accurate, though perhaps not more convenient, than that which has been adopted. The determination of the methods of intercalation best suited to make the computations in the kalendar correspond as nearly as possible with the real motions of the sun, requires all the integer numbers to be found, which most nearly express the ratio of $5^h 48^m 48^s$ to a day. These numbers are easily determined by the method of *continued fractions*. In the Gregorian kalendar, 97 days are intercalated in the course of 400 years; but it would be much more exact to intercalate 109 days in the course of 450 years. If the tropical year were precisely $365^d 5^h 48^m 48^s$, this intercalation would, indeed, be quite accurate: for $5^h 48^m 48^s$, multiplied by 450, give exactly 109 days.

337. *The reformation of the kalendar, or the change from the OLD STYLE to the NEW STYLE*, did not take place in *England*, till the year 1752, at which time it was established by an act of parliament. The alteration was ordered to be made on the 2d of September; and as the error of the Julian reckoning now amounted to 11 days, the 3d was to be counted the 14th of September.

338. *Correspondence between the days of the week and month.* As the common year consists of 52 weeks and one day, it is evident that the beginning and end of each common year will fall on the same day of the week. In a series of years, therefore, if no leap years occurred, the first day of each month would, year after year, be one day farther advanced in the week, till, in the course of seven years, the same days of the month would return to the same days of the week. But since leap year contains 52 weeks and 2 days, and occurs every fourth year, it follows that the days of the week cannot correspond to the same days of the month, till after the lapse of four times seven or twenty-eight years. This period is called the *CYCLE OF THE SUN*. When this period is completed, the sun's place in the ecliptic returns to the same signs and degrees on the same months and days, so as not to differ a degree in a century; and the leap years, as well as the common years, begin the same course over again with respect to the days of the week on which the days of the month fall. The year of our Saviour's birth, according to the vulgar era, was the ninth year of the solar cycle: hence, to find the current year of that cycle, we must add nine to the given year of the Christian era, and divide the sum by twenty-eight; the quotient will be the number of cycles which have been completed since the birth of Christ, and the remainder will be the current year of the present cycle. Thus, for the year 1829, the cycle of the sun is found to be 18. The first seven letters of the alphabet have been employed to mark the several days of the week. As one of those seven letters must necessarily stand against Sunday, it is printed in the kalendar in a capital form, and called the *DOMINICAL LETTER*: the other six letters are inserted in a different character, to denote the other six days of the week. When January begins on Sunday, A is the Dominical letter for that year: but because the next year begins on Monday, the Sunday will of course fall on the seventh day, to which is annexed the seventh letter G, which will therefore be the Dominical letter for all that year: and as the third year will begin on Tuesday, Sunday will fall on the sixth day, so that F will be the Dominical letter for that year, and so on. Hence it is evident that the Dominical letters will succeed each other in a retrograde order, viz. G, F, E, D, C, B, A. As the days of the week correspond to the same days of the month only once in twenty-eight years, it follows that it is only after the lapse of the same period, that the series of Dominical letters can proceed in the same order in reference to the days of the month. Every leap year has two Dominical letters; one answering from the beginning of January till the end of February; the other being the letter immediately preceding, answering for the remainder of the year. The Dominical letter may be found for any year of any century by the following rule: divide the centuries by 4, and take twice what remains from 6: then add together this last remainder, the odd years above the even centuries, and the fourth part of these odd years, neglecting the remainder if any: divide the sum by 7, and the excess of 7 above the remainder is the number answering to the letter required. Thus, for the year 1830, the Dominical letter

is C. For the centuries 18 divided by 4 leave 2; and twice this remainder taken from 6 also leaves 2; by adding to which the odd number of years 30, and their fourth part 7, we obtain 39: this sum divided by 7 leaves the remainder 4, which taken from 7 leaves 3, answering to C, the third letter of the alphabet.

CHAP. X.

PROPER MOTION OF THE MOON. HER PHASES. ECLIPSES OF THE SUN AND MOON.

339. *The moon*, next to the sun, is the most interesting to us of all the heavenly bodies. Her phases, or that series of changes in her figure and illumination which she undergoes in the course of about a month, are one of the most striking of the celestial phenomena; and present a division of time so remarkable that it has been the first in use among all nations.

340. *The moon has an apparent motion among the fixed stars* similar to that of the sun, but much more rapid: it carries her eastward at the rate of nearly $13^{\circ} 10\frac{1}{2}'$, at an average, in 24 hours. When this motion is accurately traced out, it is found, that the moon describes round the earth, in $27^d 7^h 43^m$, a path or orbit inclined to the ecliptic at an angle of nearly $5^{\circ} 9'$. The line in which the plane of the orbit cuts the plane of the ecliptic is called the **LINE OF THE NODES**. The point in which the moon crosses the ecliptic when *ascending* to the north, is called the **ASCENDING node**; and the opposite point, in which she crosses it when *descending* to the south, is called the **DESCENDING node**.

341. *The figure of the lunar orbit* is determined in the same manner as that of the solar, by observing the changes in the apparent diameter of the moon, and comparing these with the variations in her angular velocity. It is thus found, that the moon's orbit, like that of the sun, is in appearance an ellipse, having the centre of the earth in one of the foci, and that the radius vector, or the line joining the centres of the earth and moon, describes areas proportional to the times. Neither the line of the nodes nor the greater axis of the lunar orbit is fixed. The former has a slow retrograde motion, by which it makes an entire revolution in something more than $18\frac{1}{2}$ years; the latter has a progressive motion, by which it completes a revolution in something less than 9 years. The elliptic orbit is liable, indeed, to so many changes, that the full investigation of the lunar motion has been found one of the most difficult problems in astronomy. At the same time it is one of the most useful, as connected with the finding of the longitude of places on the surface of the earth. Accordingly, the efforts of astronomers have been assiduously directed to the perfecting of the lunar theory; and by employing the resources of modern science, and combining these with continued and accurate observation, their labours have been crowned with wonderful success.

342. *The phases of the moon* depend on her position with regard to the sun. Let E be

the earth, M the moon revolving in her orbit round the earth, E S the direction of the sun, and let us suppose all the solar rays which illuminate the moon to proceed in straight lines parallel to S E. The moon is an opaque body like the earth, and is visible only in consequence of reflecting the light of the sun. When she comes to the meridian, therefore, about the same time with the sun, that is, when she is at M, she must be invisible, on account of the unenlightened side being turned towards us. It is then said to be **NEW moon**: and, in reference to her position with regard to the sun, the moon is said to be in **CONJUNCTION**. Again, when the moon comes to the meridian about midnight, that is, when she is at *m*, she is said to be in **OPPOSITION**, and in that position she presents an entire circular disc; because the whole of the enlightened side is then turned towards the earth. It is then said to be **FULL moon**. At any point of her orbit, between the points of conjunction and opposition, the moon turns more or

less of her enlightened side towards the earth, according to her angular distance from the sun, and presents exactly the same appearances as an opaque spherical body, of which one side is illuminated, would exhibit, if viewed from a distance, and in the same positions in

which the moon is seen from the earth. After the conjunction, as soon as she has emerged sufficiently from the solar rays, she is seen in the western sky, after sunset, in the form of a **CRESCENT**, as at M' , having the convex side turned towards the sun, and the concave bounded by an elliptic line. On every succeeding night the luminous part increases, while the elliptic boundary continually approaches to a straight line. On the seventh night from the time of new moon, the moon reaches the position M'' , where her distance from the sun is 90° : she is then said to be in her first **QUADRATURE**, and exhibits the appearance of **HALF MOON**; that is, the disc is a semicircle. The enlightened part still continuing to increase on the same side, the rectilinear boundary of the semicircular disc passes again into an elliptic line, and the moon becomes **GIBBOUS**, as at M''' : on all sides the disc is convex, though it does not become entirely full orb'd until she reaches the point of opposition, at m , about the end of seven days from the time of half moon. From the instant of opposition the moon begins to return to the sun on the western side; and in her progress towards the conjunction she goes through the same series of changes in an inverted order, becoming first gibbous, as at m' ; then half moon at the time when she reaches the position m'' , her second quadrature; then a crescent, as at m''' , which, continually diminishing, at last disappears altogether. Thus, on the supposition that the moon is an opaque body and nearly spherical, and that she revolves in an orbit round the earth, the phenomena of her phases are easily explained.

343. *Strictly speaking*, the moon is not exactly 90° distant from the sun when she presents the appearance of half moon. This

phases occurs at the moment when the moon is in such a position that two straight lines drawn from her centre, — the one to the centre of the earth, the other to the centre of the sun, — form a right angle. By observing, therefore, the moon's distance from the sun, at the instant when the boundary between the enlightened and dark part exactly bisects the lunar disc, we should have in the right-angled triangle $S M F$ the angle at F ; and hence, since the side $F M$ is also known, $S F$, the distance of the sun, may

be determined. This was the first method employed for finding the sun's distance from the earth; but, from the nicety of the observations required, it cannot be expected to lead to any very satisfactory result.

344. *To a spectator on the moon* the earth must evidently exhibit a series of changes similar to the lunar phases as seen from the earth. At the time of conjunction the moon is on the illuminated side of the earth, so that the earth must then appear, as seen from the moon, an entire circular disc. Again, at the time of opposition, the moon is on the dark side of the earth; so that the earth must then be invisible. When the moon is seen as a crescent, the earth will appear gibbous; and when the moon appears gibbous, the earth will be seen as a crescent.

345. *The fact of the earth appearing to a spectator on the moon* an entire luminous disc, at the time of the moon's conjunction with the sun, furnishes an explanation of a phenomenon with which every one is familiar. In clear weather, when the moon is three or four days old, her whole body is visible. The horns of the enlightened crescent appear to project beyond the old moon as if they were part of a sphere of considerably larger diameter than the unenlightened part. Now, the part of the moon not directly illuminated by the sun is seen by the light reflected from the earth. The appearance of a lucid bow, connecting the horns of the crescent, is produced by the circumstance of the eastern edge of the moon's disc being more luminous than the adjacent regions towards the centre. With regard to the enlightened crescent appearing a portion of a larger sphere, this is an optical deception, and furnishes a remarkable proof that of two objects of equal magnitude, but of different degrees of brightness, the brighter appears larger.

346. *A lunation or lunar month is formed* by the time that elapses between one new moon and another. It consists of $29^d 12^h 44^m 3^s$ nearly; and therefore exceeds the period of her mean sidereal revolution, which is $27^d 7^h 43^m 11^s$. This excess arises from the proper motion of the sun in the ecliptic; for it is evident that the period in which the moon goes through all her phases must be equal to the time required to describe 360° , with an angular velocity equal to the difference between angular velocities of moon and sun.

347. *Cycle of the moon.* In 19 Julian solar years there are 235 lunations, and about one hour and a half more. Hence, after 19 years, the conjunctions, oppositions, and other aspects of the moon recur on the same days of the month, and only about an hour and a half sooner. This period is accordingly called the **CYCLE OF THE MOON**, and has been found of so much use in adjusting the lunar to the solar year, in order to know the time of new and full moon, and to determine the time of Easter, and other moveable feasts, that the numbers of it have been called **GOLDEN NUMBERS**. The year of our Saviour's birth, according to the vulgar era, was the first year of the lunar cycle: hence, to find the golden number, or the

current year of that cycle, we must add one to the year of Christ for which the golden number is required, and divide the sum by 19: the quotient will be the number of cycles which have elapsed since the birth of Christ, and the remainder will be the golden number or current year of the cycle.

348. *The epact* is the difference between the solar and lunar periods at the end of each year, or the moon's age on the first of January. Since the Julian solar year is $365^d 6^h$, and the lunar year, or twelve lunations, $354^d 8^h 48^m 36^s$, if we suppose new moon to have happened on the first of January, so that the epact for that year is 0, it follows that the epact for the next succeeding year will be $10^d 21^h 11^m 24^s$, or nearly 11 days. For the third year, the epact will be nearly 22 days. For the fourth year it will be 33 days, or (rejecting 30 days for a complete lunation) 3 days, and so on.

349. *The following table contains the golden numbers with the corresponding epacts adapted*

Golden Numbers.	Epacts.	Golden Numbers.	Epacts.	Golden Numbers.	Epacts.
I.	0	VIII.	17	XV.	4
II.	11	IX.	28	XVI.	15
III.	22	X.	9	XVII.	26
IV.	3	XI.	20	XVIII.	7
V.	14	XII.	1	XIX.	18
VI.	25	XIII.	12	I.	0
VII.	6	XIV.	23		

to the Gregorian kalendar, till the year 1900. The epact for each month of the year is, in like manner, the moon's age on the first day of the month, supposing new moon to have happened on the first of January.

350. *The epacts for the months of the common and leap year are as follows: —*

	Jan.	Feb.	Mar.	Apr.	May.	June.	July.	Aug.	Sep.	Oct.	Nov.	Dec.
Common year -	0,	1,	0,	2,	2,	3,	4,	5,	7,	7,	9,	9.
Leap year -	0,	1,	1,	3,	3,	4,	5,	6,	8,	8,	10,	10.

351. *It is evident that the moon's age* will be found by adding together the epact of the year, the epact of the month, and the day of the month, rejecting thirty if the sum amount to that number. Thus, if it is required to find the moon's age on the 11th November 1829; by adding 1 to 1829 and dividing by 19, we obtain a remainder 6, which is the golden number for the year 1829. Now, against VI. in the table, we find 25 for the epact of the year, and 9 is the epact for November: hence $25 + 9 + 11 - 30 = 15$, which is the moon's age; so that the moon is full on that day.

352. *The lunar cycle of 19 years*, though remarkably simple, is however far from being accurate. Nineteen years contain about an hour and a half more than 235 lunations; so that at the termination of that period the moon has advanced about an hour and a half in the next lunation. This error amounts to a day in the course of 16 cycles, or about 300 years. But, to compensate this excess, the epacts may be advanced one day every 300 years, and in this manner the lunar and solar periods will be made to agree. In consequence of her apparent motion eastward, the moon is about 48 minutes later after every diurnal revolution of coming to the meridian. As 48 minutes is equal to $\frac{4}{5}$ of an hour, an approximation is made to the time of her southing, by multiplying her age by 4, and dividing by 5. This gives the time, nearly, before or after noon, according as the moon is past the opposition or conjunction.

353. *The time of her rising and setting* is affected by the same cause. In one part of the orbit, however, this is in a great measure counteracted by the smallness of the angle which the orbit makes with the horizon. For facilitating the illustration of this phenomenon, let us suppose the moon to move in the ecliptic, from which she never deviates much more than 5° . By turning round the celestial globe, it will be seen that the ecliptic makes with the horizon very different angles, as the points of their intersection vary. If the first point of *Aries* be brought to coincide with the east point of the horizon, the angle which the ecliptic makes with the horizon is equal to the difference of the obliquity of the ecliptic and the complement of the latitude: but if the first point of *Libra* be brought into coincidence with the east point, the angle between the ecliptic and the horizon is equal to the sum of the obliquity and the complement of the latitude. When the moon is in *Pisces* or *Aries*, her motion in her orbit will therefore produce a considerable change, each succeeding night, on the distance between the east and the point of rising, but the time of rising will not be much affected. The reverse will be the case when the moon is in *Virgo* or *Libra*. Hence it is obvious that in every lunation, at a certain time, the moon must rise nearly at the same hour for several days together. This phenomenon, however, for the most part, passes unobserved; but in the harvest season it attracts attention, as being then much more conspicuous than at any other time of the year. In the autumnal months the moon is full in the signs *Pisces* and *Aries*, (the sun being at that season in the opposite signs *Virgo* and *Libra*,) and on that account rises an entire orb (or nearly so) for about a week, almost at the time of sunset, thus affording a supply of light very beneficial to the husbandman, in gathering in

the fruits of the earth. This lunation has accordingly been distinguished by the name of the **HARVEST MOON**.

354. *The inclination of the moon's orbit to the ecliptic* makes the *harvest moon* rise, more or less, nearly at the same time that she would if she moved in the ecliptic, according to the position of the line of the nodes. If we suppose the ascending node to be in *Aries*, the moon's orbit makes with the horizon an angle upwards of 5° less than the angle which the ecliptic makes with it, and consequently the harvest moon will rise more nearly at the same time than if the moon had been in the ecliptic. In a little less than $9\frac{1}{2}$ years, however, the line of the nodes will have made half a revolution, and the descending node will be in *Aries*. The moon's orbit will then make with the horizon an angle more than 5° greater than that which the ecliptic makes with it; and, consequently, the harvest moon will not rise so nearly at the same time as if the moon had been in the ecliptic.

355. *The quantity of moonlight* which we enjoy in winter is much greater than in summer. As the moon is always on the same side of the heavens with the sun, at the time of new moon, and on the opposite side at the time of full moon; it is evident that at midsummer the moon, when seen as a crescent, will rise at a point of the horizon to the north of east, and set at a point to the north of west, and will be seen high in the heavens when she passes the meridian. As she approaches full moon, however, she will rise farther and farther to the south of east, will appear low in the heavens when on the meridian, and will set farther and farther to the south of west. The reverse takes place at mid-winter: the moon is low when seen as a crescent, and rises higher and higher in the heavens as she approaches full moon. She also rises to the south of east when a crescent, and sets to the south of west; but, when full, rises and sets to the north of these points. Thus the great quantity of moonlight during the long nights of winter arises from the moon being full in the northern signs of the ecliptic, and is analogous to that of sunshine in the long days of summer. As we approach the pole, the quantity of moonlight in winter becomes still more remarkable; and at the pole itself, at mid-winter, the moon does not set for fifteen days together, namely, from the first to the last quarter.

356. *The lunar disc is diversified with a great variety of spots*, which are quite permanent, but differ very considerably from each other in degrees of brightness. These inequalities of illumination are visible to the naked eye. Since the discovery of the telescope, they have engaged the particular attention of several astronomers, by whom their relative positions have been carefully ascertained, and laid down in maps of the lunar surface. From an attentive examination of the lights and shades seen on the moon's disc, it has been inferred that her surface is very irregular, being diversified by lofty mountains, precipitous rocks, and deep caverns. The existence of these irregularities of surface is strikingly evident from the serrated appearance of the line which separates the enlightened from the dark part of the moon, and by a variety of bright detached spots, almost always visible on the dark part and near the line of separation between light and darkness. These bright spots are the tops of mountains illuminated by the sun, while his rays have not yet reached the bottom of the intervening valleys. The dark spots of the moon are smooth, and apparently level, while the luminous parts are elevated regions, which either rise into high mountains or sink into deep and immense cavities. The general smoothness of the dark spots naturally led to the conclusion that they were collections of water; but more careful observation has made it appear that the line which separates the enlightened from the dark part of the moon is not smooth and regular, even when it passes over a dark spot; so that there is no reason to suppose that there is any large collection of water in the moon: and this conclusion is strengthened by the constant serenity of her appearance, which seems undisturbed by any of those atmospherical phenomena which arise on our globe from the existence of water. The mountainous scenery of the moon, and more especially the immense caverns with which her surface is broken, bear little analogy to what we see on the surface of the earth. The resemblance may, however, be conceived to be considerably increased if all the waters of the earth were removed, and the beds of the ocean, seas, and lakes were left dry with all the inequalities of their surfaces exposed to view. The earth would then be diversified, not only with the rocks and mountains now seen upon its surface, but likewise with deep caverns of immense extent, and having detached mountains and rocks rising from the bottom, similar to the cavities discovered in the moon. From certain light spots which have sometimes been seen on the dark part of the moon, at such a distance from the enlightened portion that they could not arise from the light of the sun, astronomers have inferred the existence of volcanoes in the moon. Dr. Herschel, in particular, two or three different times, observed such spots.

arises from her orbit being inclined to the ecliptic: for it is evident that if the planes of the orbit and ecliptic coincided, the centres of the sun, moon, and earth would, at every new moon, be in the same straight line; so that the moon would be seen to pass over the sun's disc, and the sun would appear to be totally or partially eclipsed, according to the position of an inhabitant upon the earth's surface. Again, at the time of full moon, the moon is on the opposite side of the heavens from the sun; and therefore she is on the same side of the heavens with the shadow, which the earth, as an opaque body, projects into space. In most cases, however, the moon passes above or below this conical shadow; so that she is not deprived of the sun's rays. But if the plane of the orbit coincided with that of the ecliptic, the centres of the sun, moon, and earth would evidently be in the same straight line at every full moon as well as at every new moon: the moon would therefore fall into the earth's shadow, and would be eclipsed to all the inhabitants on that side of the earth which is turned towards the moon at the time.

363. *Though the inclination of the lunar orbit to the ecliptic prevents the occurrence at every new and full moon of these phenomena, there are certain distances from the nodes of the moon's orbit, called ECLIPTIC LIMITS, within which, if the moon is situated at the time of new or full moon, there will be a solar or lunar eclipse.*

364. *To illustrate the general phenomena of lunar eclipses. Let A B, D E be sections of the sun and earth, by a plane perpendicular to the plane of the ecliptic. Draw A V, B V*

touching the circles A B, D E on the corresponding sides in E and D, and meeting each other in V: also draw B G, A H, touching these circles on the opposite sides in M and N. Then, if we suppose the figure A B H G to revolve about the line C F, which joins the centres of the circles, as an axis, the cone generated by the line E V represents the shadow which the earth projects into space; and from every point of that conical shadow the light of the sun is entirely excluded. The spaces between E V, M G, and between D V, N H, will receive the light of a part of the sun: and hence the space round the shadow, which is generated by the motion of the lines G M, E V, is called the PENUMBRA.

Join C E. It is evident that the angle E V F is equal to the difference of the angles A E C, E C F. But A E C is the angle under which the sun's semidiameter is seen from the earth; and E C F is the angle under which the earth's semidiameter is seen from the sun. Both of these angles being known, their difference E V F is a given angle. Now, in the right angled triangle E V F we have given the angle at V, and the side E F, which is the earth's semidiameter: hence F V, the height of the earth's shadow, may be determined. The height of the shadow varies from 213 to 220 semidiameters of the earth.

Again, let F O be the distance of the moon from the earth: draw K O L perpendicular to F V, and join F L. The angle L F O, under which the semidiameter of the section of the earth's shadow is seen from the earth, is equal to the difference of the angles F L E, F V L. But F L E is the angle under which the semidiameter of the earth is seen from the moon, and F V L is, as has been shown, equal to the difference between the angle under which the sun's semidiameter is seen from the earth, and the angle under which the earth's semidiameter is seen from the sun: hence, to find the angle under which the section of the earth's shadow through which the moon passes in a lunar eclipse is seen from the earth, we must add together the two angles under which the semidiameter of the earth appears when seen from the sun and moon, and from the sum subtract the sun's apparent semidiameter, the remainder is the angle required. The angle L F O, when greatest, is about $46'$: but the inclination of the lunar orbit to the ecliptic is upward of 5° , and to this distance the moon may recede from the ecliptic. It is evident, therefore, that an eclipse of the moon can take place only when she is near her nodes.

365. *Let the circle A H B be the section of the earth's shadow at the moon; A B a portion of the ecliptic, and D F a portion of the moon's orbit near the ascending node. Draw C G from the centre of the shadow, (which must be the point of the ecliptic directly opposite the sun,) perpendicular to A B, and let it meet D F in G; then G is the point*

of opposition at which the moon will be 180 degrees of the ecliptic distant from the sun.

Now, in moving from D to G, the moon must enter the earth's shadow, and will therefore be eclipsed. The beginning of the eclipse will be the moment that she enters on the shadow at K: the middle of the eclipse will be the moment when her centre reaches the point E, the extremity of the perpendicular drawn from C to D F; and the end of the eclipse will be the moment when she leaves the shadow at the point L. The portion of the moon's disc that is obscured will depend on the distance between E and C, which will vanish when the point of the opposition coincides with the node. It is evident that had the eclipse happened on the other side of the

node, the opposite edge of the moon would have been immersed in the shadow.

366. *In eclipses there are various degrees of immersion.* When this is entire, it is said to be *total*; when only a part of the moon is immersed, the eclipse is said to be *partial*; and when the centre of the moon passes through the centre of the shadow, the eclipse is said to be *central* and *total*. The breadth of the shadow at the moon is about three times her diameter, so that in the case of a total central eclipse, the moon may be entirely obscured for nearly two hours.

367. *The time when eclipses shall happen may be computed* from the laws which regulate the motions of the sun and moon. This computation requires astronomical tables, and is performed with considerable labour. But it may be observed that in 223 lunations, or 18 years 10 days (or 11 days according as four or five leap years occur in the interim), 7 hours 43 minutes, the moon returns to the same position nearly with regard to the sun, and the lunar nodes, and therefore the eclipses, will return nearly in the same order and circumstances. This is thought to be the period called the *Chaldean Saros*, being used by the Chaldeans in predicting eclipses.

368. *When it is known that a lunar eclipse is to happen*, it is easy to compute its general circumstances. The distance of the moon from the ecliptic at opposition, the time of opposition, the angles under which the earth's semidiameter is seen at the sun and moon, also the apparent diameters of these two luminaries, are known from the tables. In the right angled triangle C E G we have given C G, and the angle G C E, which is equal to the inclination of the moon's orbit to the ecliptic, nearly; hence we find C E and E G. From C E and C F, the sum of the semidiameters of the section of the earth's shadow and the moon, we find E F, which is equal to E D; thence D G, G F become known. We can compute from the tables the angular motion of the moon in her orbit relatively to the sun, the latter body being supposed at rest. Her motion relatively to the opposite point C is evidently the same: hence we can determine the time of describing D G and G F; that is, the time that elapses between the beginning of the eclipse and the opposition, and between the opposition and the end of the eclipse. But the time of the opposition is known, therefore the times of the beginning and end of the eclipse will also be known.

369. *For estimating the quantity of an eclipse*, the diameter of the solar or lunar disc is conceived to be divided into twelve equal parts called *digits*; and according to the number of those parts which are obscured, so many digits are said to be eclipsed.

370. *Let it be supposed that the edge of the moon's disc just touches the edge of the section of the earth's shadow at P*, and that at the same time the diameters of the moon and shadow are each at the *maximum*, and we shall find the ecliptic limit for lunar eclipses. Produce E D and B A to meet in N: then N C is the limit of the distance of the node from the opposition at which an eclipse can happen. Since the line in which the centre of the moon moves (which for a short distance may be considered as a straight line) must be supposed parallel to the tangent to the circle A P B at the point P, the angle at E is a right angle. The angle N, is the inclination of the lunar orbit to the ecliptic: also C E is equal to the sum of the semidiameters of the moon and shadow.

Hence from the spherical triangle C E N, C N may be determined; and is found to be about $11\frac{1}{2}^{\circ}$. Unless when the node and the point of opposition, which are both liable to continual change of position, come within this distance, there cannot possibly be a lunar eclipse.

371. *Calculation of longitude.* The penumbra makes it very difficult to observe, with precision, the beginning or end of a lunar eclipse; so that though these periods may be employed for determining the longitude of places on the earth, no great degree of accuracy is to be expected. The best method is to note the time of the arrival of the boundary of the shadow at the different spots on the lunar surface, which may be considered as so many different observations.

372. *The moon seldom disappears entirely* in lunar eclipses, but is seen of a dusky red colour: even the spots on the lunar surface may be distinguished through the shade. This

effect is to be attributed to a portion of the sun's light, which enters the conical shadow in consequence of being refracted by the atmosphere of the earth. The nature and effects of atmospherical refraction will afterwards be explained.

373. *Eclipses of the sun.* With regard to the general phenomena of solar eclipses, we may begin with remarking, that when the sun's light is intercepted by the moon, so that at any place on the earth's surface he becomes partly or wholly invisible, properly speaking, it is an eclipse of *that portion of the earth* on which the moon's shadow or penumbra falls.

374. *The semi-angle* at the vertex of the moon's shadow is determined in a similar manner to that on which the semi-angle at the vertex of the earth's shadow was found. It is equal to the difference of the angles under which the semi-diameters of the sun and moon would be seen, if each of these bodies were viewed from the other at the time of their conjunction; and will therefore not be very far from being equal to the apparent semi-diameter of the sun as seen from the earth. Computing, then, the length of the conical shadow of the moon, we shall find it vary from about $60\frac{1}{2}$ to $55\frac{1}{2}$ semi-diameters of the earth. The length of the shadow at the time of the conjunction may therefore at one time exceed, and at another time fall short of the moon's distance from the earth, which varies from 64 to 56 semi-diameters. In the former case, if the conjunction happen when the moon is within a certain distance of the node, the lunar shadow will reach the earth, and a section of it will traverse a portion of the earth's surface, producing, wherever it falls, a total eclipse of the sun.

375. *Wherever the penumbra falls*, the sun will appear partially eclipsed; more or fewer digits being eclipsed according as the place is less or more removed from the shadow. Beyond the penumbra the sun is not eclipsed at all. The section of the lunar shadow is so near the vertex, that, even when greatest, the portion of the earth's surface which it covers is not very extensive, being only about 180 miles in diameter: the penumbra, however, extends over a considerable part of that hemisphere of the earth which is turned towards the sun. A total eclipse in any place cannot exceed $7' 58''$. If the vertex of the lunar shadow just reaches the surface, the total eclipse then produced will be instantaneous.

376. When the vertex of the lunar shadow falls short of the earth's surface, at no place will there be a total eclipse: but at places near the axis of the cone, there will be seen an *ANNULAR eclipse*; that is, the central parts of the sun's disc will be obscured, but a bright ring will be left visible round the dark body of the moon. Thus let A B, C D be sections of the sun and moon, and V the vertex of the lunar

shadow which is supposed not to reach the earth. Produce F V the axis of the shadow to meet the surface of the earth in E. From E draw E C G, E D H tangents to the moon, and intersecting the sun's disc in G and H. The circle of which the line joining G, H is the diameter, marks out the portion of the sun that is hid by the body of the moon from an observer at E, and the *annulus*, of which the breadth is A G, will be visible.

377. *The general circumstances of a solar eclipse may be represented by projection*; and a map may be constructed to show the progress of the shadow over the surface of the earth. The most simple projection is that which supposes the observer to be placed in the sun, and to see the path which any place on the earth's surface describes in consequence of the diurnal motion projected into an ellipse on the plane of the earth's disc, while the path of the moon's shadow is projected into a straight line on the same disc. The geometrical construction thus obtained is sufficiently accurate for the prediction of eclipses.

378. *The circumstances of a solar eclipse may, however, be computed* with considerable accuracy. Thus, find for the given place, from the tables, the time of the conjunction of the sun and moon. The position of the heavenly bodies in reference to the ecliptic is determined by latitude and longitude, in the same manner as the position of a place on the surface of the earth in reference to the equator. Find, then, for the time of the conjunction, the latitude and longitude of the moon, and apply to them the small change produced by the spectator being placed on the surface instead of the centre of the earth; a change which depends on the angle which the earth's semidiameter subtends at the sun and moon at the time: this will give us the apparent latitude and longitude of the moon as seen on the concave surface of the heavens. Compute from these and the longitude of the sun, that is, his distance from the first point of *Aries*, the apparent distance of the centres of the sun and moon at the instant of conjunction; whence we may nearly conclude the time of

the beginning and ending of the eclipse, by taking into account the apparent horary motion of the moon in latitude and longitude at the time of conjunction, computed from the tables. About the conjectured time of the beginning of the eclipse, compute two or three apparent latitudes and longitudes of the moon, and thence, combined with the longitude of the sun, the apparent distances of the centres. From these results the time may be computed by proportion when the apparent distance of the centres is equal to the sum of the apparent semi-diameters, that is, the time of the beginning of the eclipse.

379. The magnitude also of the eclipse at any time may be thus determined: let SE be the computed apparent difference of longitude of the centres S, M, of the sun and moon, and ME the computed apparent latitude of the moon. In the right-angled triangle MES, we have therefore given the two sides to find the hypotenuse MS, which, being known, we obtain mn the eclipsed part of the sun: for $mn = Sm + Mn - MS$.

380. The ecliptic limits of the sun may be determined in the following manner: let S and M (fig. 1) be the sun and moon, seen from E the centre of the earth at the moment of conjunction; that is, when their centres are in the same circle SB perpendicular to the ecliptic. Let the angle aEb , formed by tangents drawn from E to the adjacent edges of the solar and lunar discs, be equal to the greatest difference between the true place B and apparent place m of the moon, which can arise from her being viewed from the surface instead of the centre of the earth. It is not difficult to see that this difference will be greatest when the moon is in the ho-

zizon, and that its effect will be to depress her altitude. The distance of the sun is so great, that we may at present consider his true and apparent place as coincident. Suppose now an observer on the earth's surface at A, whose horizon is at right angles to SB, to have the moon in his horizon at the moment of conjunction; it is evident that to him the two discs would appear to be in contact: but to an observer on any other point of the earth's surface, the discs would appear asunder. In the moment of conjunction, therefore, the penumbra must have just touched the earth at the point A; and when the centres of the sun and moon approach nearest to each other before or after the conjunction, it will spread over a very small portion of the earth's surface near A, so as to produce barely an eclipse. Hence the distance of the sun from the node at the time of conjunction will be the solar ecliptic limit, nearly. In the right-angled spherical triangle SmN (fig. 2.) let NS be a portion of the ecliptic, and Nm a portion of the moon's orbit, N being

the node, and let the perpendicular Sm be equal to Sm in fig. 1. The arc NS is the ecliptic limit required: and to find it, we have given the angle at N equal to the inclination of the moon's orbit to the ecliptic, and Sm equal to the sum of the apparent diameters of the sun and moon together with the angle bEa , which is equal to B M m or A M E, the angle subtended by the semidiameter of the earth's disc as seen from the moon. The angle N and the perpendicular Sm being known, the base NS is easily determined. The three quantities to the sum of which Sm is equal, are variable in their values. Taking for Sm the sum of the semidiameters of the solar and lunar disc, and of the disc of the earth as seen from the moon when they are greatest, we find SN equal to $17^\circ 12'$ nearly. But if Sm be made equal to the sum of the semidiameters when they are least, SN is found to be nearly equal to $15^\circ 19'$. Within the former of these limits an eclipse of the sun may happen, within the latter it must happen.

381. If the moon's apparent diameter be greater than or equal to that of the sun, the eclipse will be total wherever the lunar shadow falls. But if the sun's apparent diameter be greater than that of the moon, the eclipse will be annular within the lunar shadow.

382. Number of eclipses. The ecliptic limits of the sun taken on each side of the node, give an arc of the ecliptic exceeding 30° , so that the sun will be more than a month in passing through these limits. Hence there must be two eclipses of the sun every year. Since the ecliptic limits of the moon, however, taken on each side give an arc only of about 23° , and since through this portion of the ecliptic the sun passes in less than a month, there may be no eclipse of the moon in the course of a year.

383. When a total and central eclipse of the moon happens, there may be an eclipse of the sun at the preceding and following conjunctions, because between new and full moons the sun describes only about 15 degrees of the ecliptic, so that each conjunction may happen within the solar ecliptic limits. The same may take place at the opposite node: there may therefore be six eclipses in the course of a year. The retrogradation of the node at the rate of 20° yearly renders it possible, when the first eclipse of the year happens early in January, that another eclipse of the sun may occur in the end of the year. On the whole, there may be seven eclipses in the course of one year; five of the sun, and two of the moon: and there never can be fewer than two, but though more solar eclipses happen than lunar, there are fewer of the former visible than of the latter; because a lunar eclipse is visible at every place on the earth which is turned towards the moon during its continuance; but in a solar eclipse the sun continues visible at all places over which the penumbra does not pass. The

greatest possible duration of the annular appearance of a solar eclipse is $12^m 24^s$, and the greatest possible time during which the sun can be wholly obscured is $7^m 58^s$.

384. *As the beginning and end of a solar eclipse can be observed with considerable accuracy, they are useful for determining the longitude, though the method which they furnish is complex and laborious.*

385. *Table showing the Time of all the Solar Eclipses which will be visible in this Country during the present Century. The Hour and the Digits eclipsed are adapted to the middle of England.*

386. *Effects of atmospherical refraction and parallax.* In the preceding explanation of solar eclipses we have had occasion to refer to the effects of ATMOSPHERICAL REFRACTION; also to the difference between the apparent places of the sun and moon, called their PARALLAX, produced from their being viewed from the surface instead of the centre of the earth. Before leaving this subject, we shall state a little more fully the effects arising from these causes.

387. *Atmospherical refraction.* The earth is surrounded on all sides by an æriform elastic fluid, which is called the ATMOSPHERE. This fluid possesses weight, and is compressible; and hence the parts near the surface of the earth are more dense than those above them, on account of the greater superincumbent pressure which they sustain. The same thing holds true of every stratum when compared, in reference to density, with that immediately below it; so that from the surface upwards the density gradually diminishes, at a few miles' elevation becomes very small, and at some point may be considered as altogether evanescent. Now, it is a well known principle, that if a ray of light, after passing through one medium (air, for instance), enters another (say water) of a different density, in a direction not perpendicular to its surface, it is bent out of its course towards the perpendicular to the surface on which the ray is incident, if the second medium is the denser of the two; but from that perpendicular if the second medium is the rarer. In passing through the atmosphere, therefore, a ray of light will be continually deflected from the rectilineal into a curvilinear path; because at every point of its course it is entering a medium of a greater density. The ray is said to be *refracted*; and as the tangent drawn from the eye to the curve which it describes is the direction in which celestial objects appear, it follows, that refraction renders the apparent altitude of all the heavenly bodies greater than the true. Hence they often appear above the horizon when they are actually below it.

388. *The deviation of the refracted ray from its original course increases with the angle of incidence, and vanishes when the direction of the ray is perpendicular to the surface of the second medium.* Hence atmospherical refraction is greatest when the object is in the horizon, where it may be about $34'$: at 45° altitude, it is about $57\frac{1}{2}''$: in the zenith it vanishes.

389. *Whatever alters the density of the atmosphere must affect also its refractive power.* In all accurate observations, therefore, the state of the barometer and thermometer must be taken into account. At the same zenith distances, the quantity of refraction varies nearly as the height of the barometer, supposing the temperature to remain the same. The effect of a variation in the temperature is to diminish the quantity of refraction about $\frac{1}{350}$ th part for every increase of one degree in the height of the thermometer.

390. In passing through the atmosphere light is reflected as well as refracted. The reflective power of the atmosphere produces the splendour of day by diffusing light in every direction. Combined with its refractive power, it causes that faint light called TWILIGHT,

which is perceived before sunrise and after sunset;—beginning in the morning in our latitude, and ending in the evening, when the sun's depression below the horizon is about 18° . Various other phenomena are to be attributed to the same cause: the red and orange colour of the morning and evening clouds; the ruddy appearance of all the heavenly bodies when near the horizon; the blue colour of the sky; and the bright azure of the distant mountain, are all the effects of the refractive and reflective powers of the atmosphere.

391. Refraction is also the cause of *the oval appearance of the sun and moon when near the horizon*. The diameter of the disc that is parallel to the horizon remains unaffected in its apparent length, because both extremities are equally refracted; but the diameter perpendicular to the horizon is shortened by about $\frac{1}{8}$ th of its length, because the lower edge of the disc, being nearer the horizon, is refracted nearly five minutes more than the upper.

392. *The great apparent magnitude of the sun and moon when in the horizon* is another remarkable phenomenon which we may here notice. This allusion, which is altogether optical, is usually accounted for on this principle, that we form an erroneous judgment respecting the distances of these bodies when they are in the horizon, compared with their distances when they have attained a considerable elevation. When we see the moon, for example, in the heavens at a considerable altitude, we intuitively suppose her nearer than when she is in the horizon; because, in the latter case, we see a multitude of objects,—many of them at great distances, and the moon beyond them all; but, in the former case, we have no intervening objects by which to form an estimate of her distance. The angle under which she is seen being nearly the same, we infer a greater magnitude when we imagine the distance greatest, that is, when the moon is in the horizon. Such is the error into which we, in this instance, fall, in the rapid judgments of the mind respecting magnitude and distance connected with vision. The more deliberate conclusion on this subject drawn by reason is, that the moon must indeed be at a greater distance from an observer on the earth, when she is in his horizon, than when she is in or near his zenith; but that, however the eye may be deceived, her apparent diameter must, when exactly measured, be found less. This is accordingly the case; for, when accurately measured with the micrometer, the moon's apparent diameter, when she is in the horizon, is actually found to be less than when she has attained a considerable altitude.

393. *Parallax*. We have formerly shown that, in comparison with the distances of the fixed stars, the earth is but as a point in the universe; so that their positions in the heavens appear the same when viewed from the earth's surface, as they would if they were viewed from its centre. This, however, is not the case with regard to the sun, moon, and planets. At each of these bodies the earth presents a disc of an appreciable magnitude: and, on the other hand, their positions among the fixed stars, when viewed from different points of the surface of the earth, vary, and are different from what they would be were they seen from the centre of the earth.

394. Let ABE (*fig. 30.*) be the earth, C its centre, and M, M'', M' (a heavenly body, for example) the moon in the sensible horizon, the zenith, and any intermediate position. The true places of the moon in these positions, as seen from the centre C , and referred to the starry heavens, will be m, m'', m' ; and their apparent places, as seen from B , will be n, n'', n' . It is evident, that in the zenith the true and apparent places coincide, so that there is no parallax. In the horizon the parallax is greatest: it is measured by the arc mn , and is equal to the angle BCM , under which the semidiameter of the earth's disc appears when viewed from the moon. At the intermediate position M' the parallax is measured by the arc $m'n'$: it is less than in the horizon, and decreases as the body ascends until it vanishes when the body reaches the zenith. From the horizon to the zenith, parallax diminishes the apparent altitude of a body; but as the altitude increases, this diminution becomes less and less. Its effect, therefore, is contrary to that of refraction, which always increases the apparent altitude of a body.

as the altitude increases, this diminution becomes less and less. Its effect, therefore, is contrary to that of refraction, which always increases the apparent altitude of a body.

CHAP. XI.

MOTION OF THE PLANETS ROUND THE SUN.

395. *The phenomena of the motions of the other planets differ from those of the moon*, which, as we have shown, are all easily accounted for, on the supposition that the moon revolves round the earth in an elliptic orbit, subject to various changes; which are confined, how-

ever, within certain limits. The attempts which the ancient astronomers made to explain the celestial phenomena, by supposing the earth to be the centre of the universe, introduced a system, the *PTOLEMAIC*, which was received for about 1500 years, as affording the true explanation of the planetary motions; but which the progress of scientific discovery has proved to be absurd. Ptolemy, an astronomer of Egypt, who flourished about 140 years after the Christian era, supposed the planets to revolve about the earth in the following order; viz. the Moon, Mercury, Venus, the Sun, Mars, Jupiter, Saturn. Beyond the region of the planets he placed the sphere of the fixed stars. While he thus accounted for the proper motions of the planets from west to east, he conceived the whole to be carried round the earth by a diurnal motion, in the opposite direction, in twenty-four hours. The irregularities of the planetary motions, — these being sometimes direct, at other times retrograde; sometimes swift, and at other times slow, — were imagined by him to arise from each planet moving in a small circle, called an *EPICYCLE*, whose centre was carried round a larger circle, called the *DEFERENT*, having the earth placed a little to the one side of its centre. The motions in these circles he imagined to be produced by the revolution of transparent globes; each planet being supposed to be attached to a globe, which carried it round in its epicycle; and this globe again supposed to be contained in the shell of another globe of sufficient thickness to receive it within its solid substance, and to allow it to revolve on its own centre, at the same time that it was carried in the deferent round the earth.

396. *Setting aside the obvious objections to this theory*, arising from the extravagance of the suppositions, as well as the awkwardness and complication of the machinery which it employs, an insuperable difficulty remains; viz. that the whole system is entirely hypothetical, and offers no proof of the existence of the agents to which it attributes such mighty effects. It is not surprising, therefore, that instead of being confirmed by subsequent discoveries, it fell to the ground as soon as the true method of investigating the laws of nature was understood and adopted.

397. *Of the planets two, Mercury and Venus*, always accompany the sun, never receding from him beyond certain limits: the rest are seen at all possible angular distances from the sun. Let us, then, fix upon Venus as the most conspicuous of the two which accompany the sun, and upon Mars as one of the most conspicuous among those which recede to all angular distances from him; and by tracing out the apparent motions of these planets, let us endeavour to ascertain the centre about which they revolve.

398. *When the planet Venus* is near the sun, she is invisible; but when she has emerged sufficiently from his rays, she is seen in the twilight of the morning or evening, according as she is to the west or east of the sun. In the former case she is the *MORNING STAR*; in the latter, the *EVENING STAR*. When she begins to be seen in the evening, she is found to be receding from the sun towards the east, and thus disengaging herself more and more from his rays. Having reached her greatest angular distance, or elongation, which is from 45° to 48° , she begins again to approach him, and continues to do so till her angular distance is about 28° . During all this time her motion is *direct*, that is, in the order of the signs; but now she becomes *stationary*, and in a short time she is seen moving in a direction contrary to the order of the signs, and has thus acquired a *retrograde* motion; but still she continues to approach the sun, until in a short time she is lost in his light. After being invisible for about six weeks, she is again seen; but now in the morning to the west of the sun, emerging from the solar rays. Her motion is still retrograde; but when she has reached about 28° distance from the sun, she again becomes stationary; and in a short time resumes a direct motion, receding from him night after night, until her angular distance exceeds 45° . She then returns to the sun; is for a time lost in his rays; and at length is seen in the evening to the east of the sun, to repeat the same round of phenomena. While Venus thus appears to have an oscillatory motion to the east and west of the sun, she is found, when viewed through a telescope, to present phases exactly similar to those of the moon, the illuminated portion being always turned towards the sun. We may hence infer that Venus is an opaque body, and shines in consequence of reflecting the solar light. At the same time her apparent diameter also varies, its variations having an evident relation to the position of the planet with regard to the sun. The diameter appears least when the planet is about to be immersed in the rays of the sun in the morning, or immediately after her emerging from them in the evening. On the other hand, it appears greatest when she is about to be lost in the solar rays in the evening, or when she emerges from them in the morning. Such is a general view of the apparent motion of Venus; and by attending to the phenomena which she exhibits, we are led to the conclusion that she revolves round the sun. When in the morning she begins to disengage herself from the solar rays, she is seen to rise before the sun in the form of a crescent; and it is then that her diameter appears greatest. At that time, therefore, she must be nearer to us than the sun is, and not far from being in conjunction with him. Her crescent increases, and her diameter diminishes, as she recedes from the sun: when she has reached her greatest elongation and returns again towards him, she continues to discover to us more and more of her enlightened hemisphere,

her diameter all the time diminishing, until she is lost, in the morning, in the sun's rays. At the instant of her disappearing, Venus is seen as a full disc; and at the same time her diameter is least. Hence we may with certainty infer, that she is then at a greater distance from us than the sun, and again nearly in conjunction with him. After having remained for some time invisible, she re-appears in the evening to the east of the sun; and in receding from and returning towards him exhibits, in an inverted order, the same phenomena, in reference to the changes in her disc and apparent diameter, which she had presented when seen in the morning, on the west of the sun: her enlightened hemisphere turns more and more from us, and her apparent diameter continually increases, until she again disappears, or is seen as a black spot traversing the disc of the sun.

399. *From these phenomena* only one inference can be drawn; viz. that Venus revolves in an orbit, near the centre of which the sun is placed. This conclusion, which rests on the firm basis of observation, leads to a natural and simple explanation of all the peculiarities of her motion.

400. *The planet Mars*, the next to be considered, appears to be carried round the earth by a motion which is subject to great inequalities. When he begins to be seen in the morning emerging from the solar rays, his motion is direct, and at its greatest rapidity; but it gradually diminishes until the planet's angular distance from the sun is about 137° . At that time it changes into a retrograde motion, whose rapidity increases till the moment that the planet comes into opposition with the sun, or is on the meridian at midnight. It is then at its greatest rate, and presently begins to decrease, continuing to do so till the planet becomes stationary when at the angular distance of about 137° from the sun. The motion now returns to its direct state, after having been retrograde for about seventy-three days; and in that period the planet describes an arc of retrogradation of about 16° . Mars continues to approach the sun, until he becomes immersed in his rays in the evening. These phenomena are repeated at every opposition of the planet, with considerable differences, however, in reference to the duration and extent of the retrogradations. At different points of his course round the heavens, the apparent diameter of Mars is very different: it varies from about $13.3''$ to $29.1''$. It is greatest when the planet is in opposition to the sun.

401. *The phenomena now described can be satisfactorily explained* in no other way but by supposing Mars to revolve round the sun. As he recedes from the sun to all possible angular distances, the earth must be situated within his orbit; but the increase of his apparent diameter as he approaches his opposition, and its decrease when he approaches the sun, show that the earth is not the centre of his motion. Before he reaches the point of opposition, his motion, from being direct, becomes retrograde; after the opposition it resumes its direct state, when the planet is at the same distance from the sun, at which he was situated when the motion became retrograde; and it is at the moment of conjunction that this last motion is most rapid. Now, all these circumstances evidently indicate that the apparent motion of Mars is the result of two combined motions, which alternately conspire with and oppose each other, and of which one depends on the apparent motion of the sun. As we have found that Venus revolves round the sun, and accompanies him in his apparent annual motion round the earth, we are led by analogy to extend the same law to Mars, and to conclude that he also revolves in an orbit round the sun.

402. *The disc of Mars changes its figure*, and becomes sensibly oval, according to his position relatively to the sun: hence we may conclude that Mars is an opaque body, and derives his light from the sun.

403. *The same reasoning being applicable in the case of the other planets*, we may extend to all of them the conclusion which we have now established in reference to Venus and Mars, — namely, that they are opaque bodies, and revolve about the sun in orbits nearly circular; while that luminary of the system either describes or appears to describe an orbit about the earth in the course of a year. This general law, which affords a simple and complete explanation of the planetary motions, receives additional confirmation from the phenomena of the satellites of Jupiter and the ring of Saturn; for these phenomena prove directly that Jupiter and Saturn revolve about the sun in nearly circular orbits.

CHAP. XII.

MOTION OF THE EARTH ROUND THE SUN.

404. The conclusion to which we have now been led, — that all the planets describe orbits that have the sun near to their centre, — naturally suggests the question, whether the earth itself is not subject to the same law, and therefore to be ranked among the planets which

revolve round the sun. With regard to the celestial motions, every appearance would remain the same to us, whether the earth described an orbit round the sun, or the sun with his accompanying planets revolved round the earth. To which of these hypotheses the preference is due will appear from the following considerations : —

405. *The immense masses of the sun and of several of the planets, combined with their great distances from the earth, render it much more simple to suppose that the earth describes an orbit round the sun, than that the whole planetary system revolves round the earth.* What an inconceivable rapidity of motion is it necessary to assign to Saturn, almost ten times more distant from us than the sun, or to Uranus, at about double the distance of Saturn, in order that these planets may complete a revolution round the earth in a year, at the same time that they revolve about the sun ! It is a law which is found to pervade the planetary system, that the less body revolves about the greater body which is in its neighbourhood ; and by supposing the earth, in conformity with this law, to revolve about the sun, which in magnitude greatly exceeds all the planets taken together, we avoid all the complication and rapidity of motion which follow from the supposition of the earth being at rest.

406. *The analogy which subsists between the earth and the planets confirms the hypothesis of the earth being carried round the sun by a motion of translation :* Jupiter, for example, is known to have a revolution on his own axis, and to be attended by four satellites. In these particulars the earth resembles that planet, having also a revolution on its own axis, and being attended by one satellite, the moon. An observer placed on Jupiter would be led from appearances to imagine that the planetary system revolved round him, in like manner as an inhabitant of the earth supposes himself placed at the centre of the celestial motions : and the greater magnitude of Jupiter would give to such a conclusion, when drawn by an observer placed on that planet, a greater resemblance to the truth than it would have when drawn by an inhabitant of the earth. With such a close analogy in these respects before our eyes, may we not naturally conclude that it extends still farther ; and that as Jupiter revolves in an orbit round the sun, the earth must also have a similar motion ?

407. *Let us imagine ourselves to be placed on the surface of the sun, and from that position to observe the earth and the planets.* All these bodies would appear to move from west to east ; the planets would be found free from all that complication in their motion to which they appear subject when viewed from the earth ; and the motion of the earth itself would in every circumstance correspond with that of the planets. The more distant a planet is from the sun, the longer is the time which it requires to perform its revolution round him ; but throughout the planetary system this remarkable law prevails, connecting the periodic times with the distances, — the squares of the former are proportional to the cubes of the latter. If we compute, by this principle, what should be the time of revolution of a planet situated at the distance of the earth from the sun, we find the result correspond exactly with the sidereal year ; thus, the earth's distance from the sun being assumed as unity, the distance of Mars is known to be 1.523693 : his periodic time is 686.9796 days. Hence we have $(1.52693)^3 : 1^3 :: (686.9796)^2 : (365.256)^2$. The periodic time of a planet, at the same distance from the sun as the earth is, should therefore be 365.256 days, which is the length of the sidereal year. This result leaves no doubt that the motion which the earth would be seen to have, if it were viewed from the sun, arises from the same causes, and is regulated by the same laws as the motions of the planets : hence we may conclude that it is no less real.

408. *The motion of the earth in an orbit round the sun, which the preceding considerations render so highly probable, is directly proved by the phenomena of the aberration of light.* It was long supposed that light was propagated from the sun and other luminous bodies instantaneously ; but modern observations have proved that this hypothesis is erroneous, and that light, like all other projectiles, occupies a certain time in passing from one point of space to another. The fact that light has a progressive motion was first discovered by Roemer, a celebrated Danish astronomer, from observations made on the eclipses which the satellites of Jupiter undergo when they fall into his shadow. He found that these eclipses happened sometimes sooner and sometimes later than the time deduced from the tables of their motions ; the observation being before or after the computed time, according as the earth was nearer to or farther from Jupiter than the mean distance. Repeated observations have proved, that when the earth is between the sun and Jupiter, his satellites are seen eclipsed about $8\frac{1}{4}$ minutes sooner than they should be according to the tables ; but that when the earth is on the opposite side of the sun from Jupiter, the eclipses of his satellites happen about $8\frac{1}{4}$ minutes later than the time shown by the tables. The only conclusion that can be drawn from these facts is, that light occupies about $16\frac{1}{2}$ minutes in traversing a space equal to the diameter of the earth's orbit, which is upwards of 190 millions of miles ; it must therefore move at the enormous rate of nearly 210,000 miles in a second.

409. *Now, if the earth is really in motion, it must be moving at the rate of about 20 miles in a second, in order to accomplish its revolution round the sun in the course of a*

year. This rate of motion, although small when compared with the velocity of light, bears to it a sensible proportion; so that an evident consequence of the earth's motion will be, that the apparent places of the heavenly bodies will not be the same as they would be if the earth were at rest.

410. Suppose AB to be a portion of the earth's orbit, S a fixed star, and SA the direction of light proceeding from the star to the earth at A . It is evident that if the earth were at rest at

A , a telescope presented in the direction AS would receive the light of the star, which, proceeding along the axis of the telescope, would reach the eye at A , and show the star in its true position. But if the earth be supposed to move from A towards B with a velocity that bears a sensible proportion to the velocity of light, the ray SA , which enters the telescope at C , cannot reach the eye, but must, in consequence of the motion, be lost against the interior of the tube. In order that the light from the star may reach the eye when carried forward by the earth's motion, the telescope must have such an inclination to AB , that SF being supposed a ray parallel to SA , and meeting the axis of the telescope in D , AF may have to FD the same ratio as the earth's velocity in its orbit has to the velocity of light; that is, of 1 to 10,000

nearly. In this position of the telescope, the light entering at D will pass along the axis as it moves from A to F , and will reach the eye at F ; but the star will be seen in the direction, not of FS , but of FE : so that its apparent place differs from its true by a quantity measured by the angle SFE or ADF . The angle DFE is the aberration which will evidently be towards that part of the heavens to which the earth is moving. Let the axis FE be supposed to be produced to the starry heavens: it will trace out on the convex surface a circle, if the star S is in the pole of the ecliptic; but an ellipse in every other position of the star. The true place of the star is the centre of the circle or ellipse.

411. If the star be in the pole of the ecliptic, the angle DAF may be considered as a right angle; for the line joining the star and the earth will always be perpendicular to the direction of the earth's motion. In this case, therefore, the angle ADF will be the greatest possible; for the ratio of $\sin. ADF$ to $\sin. DAF$ is constant, being the same with the ratio of AF to FD , or of 1 to 10,000 nearly: so that $\sin. ADF$ is greatest, and therefore ADF is greatest when $\sin. DAF$ is the greatest possible; that is, when DAF is a right angle. In the case of any other star the greater axis of the ellipse which it appears to describe round its true place as a centre will be equal to the diameter of the circle which a star in the pole of the ecliptic would appear to describe about the pole as a centre: for the ellipse will be the orthographic projection of a circle equal to that described about the pole, the greater axis being the diameter, which is perpendicular to a circle of the sphere passing through the star and the pole of the ecliptic, and at right angles to the ecliptic. When the star is in the ecliptic, it will appear to describe an arch equal to the greater axis of the ellipse described by a star not in the ecliptic, or to the diameter of the circle of aberration that would be described by a star in the pole of the ecliptic.

412. When angle DAF is a right angle, we have $DF : FA :: \text{rad} : \sin. \angle ADF$; that is, $10,000 : 1 :: 1 : .0001 = \text{sine of greatest aberration}$, which will therefore be $20''$ nearly. The aberration of a planet will depend on its own motion as well as on that of the earth. If the motion of the planet were equal and parallel to that of the earth, no aberration would take place. The aberration of a planet may be found by first considering the effect of the motion of the earth on the apparent place, and then the aberration arising from the planet's own motion.

413. Such are the effects which, if the earth have actually a motion of translation that carries it in an orbit round the sun, must arise from that motion combined with the progressive motion of light. To obtain, therefore, decisive proof of the earth's annual motion, it is only necessary to ascertain by accurate observation the existence of these phenomena.

414. The true system of the world, which supposes the sun to be at rest in the centre, and the earth and planets to revolve round him, while the moon revolves about the earth, and the diurnal motion of the heavens arises from the motion of the earth on its axis, was taught by several of the ancient philosophers, and particularly by Pythagoras. It was also held by Archimedes; but after him it was neglected, and even forgotten for many ages, until at length, in the beginning of the sixteenth century, it was revived and improved by Copernicus, from whom it took the name of the COPERNICAN System. Notwithstanding the beauty and simplicity which distinguish this theory, it was at first coldly received or utterly rejected. Tycho Brahe, an illustrious Dane, was among its adversaries. He regarded the doctrine of the earth's motion as untenable, without abandoning the testimony of Scripture: hence he was led to imagine another system, which bears his name; in which the sun, with all the planets and comets revolving round him, is supposed to perform a revolution about the earth in a solar year, while at the same time all the heavenly bodies are supposed to be carried round the earth from east to west in twenty-four hours.

415. The only apparent difficulty connected with the Copernican system arises from the fact, that the earth's axis is always pointed to the same star, and that the stars preserve always the same relative positions; though by the annual motion of the earth, a spectator on its surface views them at any two instants of time separated by the period of about six

months, from two points nearly 200,000,000 miles asunder. During the seventeenth century the supporters of the Copernican system laboured to remove this objection, by detecting a change in the position of the fixed stars.

416. *The minute and accurate observations* instituted for this purpose led, in the end, to the important discovery made by the celebrated Dr. Bradley, that the very effects which we have shown, must result from the annual motion of the earth combined with the progressive motion of light. He found that each star describes, round its true place as a centre, a small ellipse of which the greater axis is about $40''$; and that this ellipse approaches to a circle or to a straight line, which are its limits, according as the star is situated towards the pole of the ecliptic, or towards the ecliptic itself. No parallax is observable in the fixed stars arising from the earth's annual motion; and hence it must be inferred that their distance is so great, that even the diameter of the earth's orbit is to be regarded as a point in the universe.

417. From an attentive consideration of the celestial motions, *we are therefore led to reject as erroneous the notions which appearances at first suggest respecting the system of the world.* Instead of the globe which we inhabit being at rest in the centre of the universe, it is a planet in motion about its own axis and about the sun. In regarding it under this aspect, we find all the celestial phenomena explained in the most simple manner, the laws of the motions of the heavenly bodies appear uniform, and every analogy subsisting among them is preserved unbroken. Like Jupiter, Saturn, and Uranus, the earth is accompanied by a satellite; it revolves on its own axis as Venus, Mars, Jupiter, Saturn, and perhaps all the planets; like them it receives light from the sun; and to complete the analogy, it revolves about the sun in the same direction, and according to the same laws. By following out the results arising from the earth's motion being combined with the real motions of the planets and of light, we find all the phenomena of the heavens flow, as necessary consequences, from one great principle. Thus the motion of the earth acquires all the certainty of which a physical truth is susceptible.

418. *The vicissitude of season* arises, as we have already explained, from the obliquity of the ecliptic to the equator. The ecliptic, which we have hitherto considered as the path of the sun round the earth, we have now proved to be the orbit of the earth round the sun. The axis of the earth's diurnal motion is inclined to the plane of its orbit at an angle of about $66^{\circ} 32'$, and remains, as the earth revolves round the sun, nearly parallel to itself. Hence the circle which the sun appears to trace in the heavens in the course of a year forms with the equator an angle of about $23^{\circ} 28'$. This produces the differences in the distribution of the solar light and heat which we observe throughout the seasons of the year.

419. *The parallelism of the axis is not absolute*; for the axis is found to have a slow motion of revolution from east to west round a line passing through the centre of the earth, and perpendicular to the ecliptic; its revolution being completed in the period of 25,745 years. In consequence of this motion the poles in the sphere of the starry heavens describe each a circle round the pole of the ecliptic, at the distance of $23^{\circ} 28'$ nearly; and the two points in which the terrestrial equator, when produced to the starry heavens, cuts the ecliptic shift to the westward, at the rate of about $50\frac{1}{2}$ seconds yearly, which causes the precession of the equinoxes. A small inequality has been observed in the precession of the equinoxes, and in the mean obliquity of the ecliptic, which arises from a slight motion in the earth's axis, whereby its inclination to the ecliptic is not always exactly the same, but varies backwards and forwards some seconds. This is called the nutation of the earth's axis, and was discovered by Dr. Bradley while employed in verifying his theory of aberration. The period of the changes of this inequality is nearly nine years.

CHAP. XIII.

ORBITS OF THE PLANETS.

420. *To an observer placed on the sun* all the planets would appear to trace on the concave surface circular paths, cutting each other at various angles, but all comprehended within a certain zone of the heavens of some degrees in breadth. The angle which the plane of the orbit of a planet makes with the ecliptic is called the *INCLINATION* of that orbit; and the line of their intersection is called the *LINE OF THE NODES*. If a planet be observed twice in the same node, the node being supposed to have in the mean time remained stationary, the position of the line of the nodes can be determined, and also the distance of the planets from the sun at the times of observation.

421. Let a superior planet be observed in its node N from the earth at E, and after the planet has made an entire revolution let the earth be at E'. Then, from the time and the theory of the earth's motion, EE' is given, and the angles SEE', SE'E. But the angles SEN, SE'N are known by observation; therefore, in the triangle EE'N, the angles EE'N, E'EN, and the base EE' are given; and hence the sides EE' and E'N may be found. Wherefore from either of the triangles SEN, SE'N the distance SN is determined; also the angle ESN, which ascertains the position of the node as seen from the sun.

422. From observations of this kind, made at times considerably distant from each other, it is found that the nodes of each planet have a slow retrograde motion.

423. Again, the distance of a planet from the sun, and its place as seen from the sun, may be determined from observations made at the time of its opposition to the sun.

424. Let E be the earth, S the sun, P the planet, O its place reduced to the ecliptic, SN the line of the nodes passing through the sun. Since the planet is in its opposition, the points S, E, O are in the same straight line. The angle ESN is known by last problem, which determines the position of the line of the nodes; therefore the arch ON in the heavens, which measures it, is also given. The angle PNO is equal to the inclination of the planet's orbit to the ecliptic, and is therefore given; also the angle PON is a right angle. Hence in the spherical triangle PNO, the perpendicular PO and the hypotenuse PN may be found. Now the arc PO is the measure of the angle PSO, and PN is the measure of PSN; therefore these two angles are given. In the rectilinear triangle PSE, the exterior angle PEO can be determined by observation; the angle PSE or PSO is given, and the base ES is known by the theory of the earth's motion; whence PS, the distance of the planet from the sun, may be computed.

425. *Orbit of a planet.* Since the angle PSN is also known, the line PS is given in position as well as in magnitude. If many oppositions of a planet are thus observed, and if the radii obtained be laid down, the line connecting their extreme points will represent the orbit of the planet. In this manner it is found that the orbits of all the planets are ellipses, having the sun in their common focus; and that the angular motions of a planet round the sun are inversely as the squares of its distance from the sun: so that the sectors described by the radius vector are proportional to the times. This exactly corresponds with what was proved respecting the apparent motion of the sun in the ecliptic, and therefore the motion of the earth is regulated by the same law.

426. The planets which move immediately round the sun are called PRIMARY, their satellites are called SECONDARY PLANETS. Thus, the moon is a secondary planet to the earth. In considering the lunar motion, we found that the moon describes round the earth an elliptic orbit, and that the radius vector describes equal areas in equal times. The same holds of the satellites of Jupiter, Saturn, and Uranus; so that the same principle runs through the motions of all the bodies of the planetary system.

427. When the mean distances of the planets are compared, and also their periodical times, it is found that the squares of the periodic times are as the cubes of the distances.

428. The great general facts which have now been pointed out respecting the orbits of the planets, and their motions in these orbits, were first discovered by Kepler, after he had employed immense labour and ingenuity in the research, and are usually called KEPLER'S LAWS. It may be proper to bring them under one point of view:—

I. The primary planets all revolve in elliptic orbits round the sun, which occupies one of the foci of the ellipse; the plane of the orbit passing through the centre of the sun.

II. The radius vector describes equal areas in equal times.

III. The squares of the times of revolution in the planetary bodies are as the cubes of their distances from the sun.

CHAP. XIV.

COMETS.

429. The fixed stars and the planets are always visible when not obscured by the superior light of the sun; but the class of bodies called COMETS are seen only when they are in that part of their several paths which lies nearest to the sun: at all other times they move through regions of space far beyond the reach of our vision, even when assisted by the most powerful telescopes. The motions of the comets are, like those of the planets, performed in elliptic orbits according to Kepler's laws; but, unlike the planetary orbits, the ellipses which the

comets describe are extremely elongated: so that the small portion of their orbits through which we have an opportunity of tracing them coincides very nearly with a parabola, the curve of which is the limit of the ellipse when its greater axis is indefinitely increased. The inclinations of the orbits of the comets is very various; some move in planes almost coincident with the ecliptic, and others in planes nearly perpendicular to it. They move also in very different directions; the motion of some being *direct*, and of others *retrograde*.

430. *The comets differ widely from the planets in their appearance*, as well as in the figure and position of their orbits. When a comet is first seen, it is usually surrounded by a faintly luminous vapour, which becomes more bright as the comet approaches the sun, and at length shoots out into a long luminous and transparent train, very much resembling a *streamer*, and extending in a direction opposite to the sun. The dense part of the comet, which both to the naked eye, and when viewed through a telescope, resembles much the planetary bodies, is called the *nucleus*; the faintly luminous vapour by which it is surrounded is called the *coma*; and the long luminous train proceeding from the comet in an opposite direction from the sun is called the *tail*. Between the nucleus and the coma lies a part fainter than the former, but brighter than the latter, and in which the nucleus appears involved: this is called the *head* of the comet.

431. *The length of the tail* is very various. Sometimes it extends only a few degrees; in other cases it has been found to reach over more than a fourth part of the heavens. If a comet does not come very near the sun, the coma does not shoot into a tail, but retains the appearance of a nebulosity round the comet during the whole period of its being visible. The tail sometimes consists of two or more diverging streams of light, and is always so transparent that the smallest stars are seen through it without any sensible diminution of their brilliancy.

432. *Nature of comets.* In ages of ignorance comets have always, from their extraordinary appearance, been sources of superstitious terror to mankind. This fear has been dissipated by the light of science, which has shown that the appearances of comets are regulated by the same laws as other celestial phenomena. We are still, however, almost entirely ignorant of the nature of these bodies, though a great many hypotheses have been formed concerning them. They were considered by some of the ancients, and particularly by Aristotle, as accidental fires or meteors generated in the atmosphere of the earth; but this opinion is obviously groundless. If they were connected with the earth or its atmosphere, they would partake of the diurnal motion on the axis, and could not therefore appear to have a diurnal revolution in the heavens along with the other celestial bodies. Besides, their having no diurnal parallax proves that they are at a great distance from the earth; while the fact of their apparent motion being affected by the annual motion of the earth shows that they are situated in the planetary regions. Observation has demonstrated that, like the planets, they are permanent bodies, and, in all probability, derive their light from the sun.

433. *From the small portion of the orbit of any comet* which we have an opportunity of observing, we cannot ascertain with sufficient accuracy the elements necessary for determining the period of its return; but supposing that their orbits are not disturbed by any cause in those distant regions of space through which the greater portion of the paths of comets lie, it is evident that by accurately observing all the comets that come within view, and carefully recording the results, in the course of ages the return of many comets may be detected and their periodic times ascertained. Hence the greater axis of the orbit of each may be determined by Kepler's third law; and the comet's least distance from the sun being found by observation, the less axis will also become known. In this manner the periodic time of some comets has been found, and their return predicted.

434. *The first and most remarkable instance* is that of Dr. Halley, who, by comparing his observations on the comet of 1682, with those of Kepler on the comet of 1607, and those of Apian on the comet of 1531, found reason to conclude, from the agreement of the circumstances of each, that what had been considered three distinct comets were only re-appearances of the same comet after a period of about 76 years. In all the three cases the distance of the comet from the sun when nearest to him was almost the same; the position of the comet in the heavens at the time of its nearest approach to the sun likewise corresponded; as did also the inclination of the orbit, the place of the nodes, and the variableness of the motion, as being direct or retrograde.

435. *These coincidences* rendered the identity of the comet almost absolutely certain. Hence Halley predicted its return in the end of 1758 or the beginning of 1759. The comet appeared about the end of December 1758, and made its nearest approach to the sun on the 13th of March 1759, differing not many days from the time expected. There is, therefore, a degree of probability approaching to certainty, that it will again make its appearance at the completion of its period in the year 1835.

436. *Though there can be no doubt* of the identity of the comet of 1531, 1607, 1682, and 1759, the appearances were considerably different. In 1531 the comet was of a bright gold colour; in 1607, it was dark and livid; it was bright again in 1682; and obscure in 1759.

437. *The mean distance of this comet from the sun* is about eighteen times that of the earth; but in consequence of the great eccentricity of its orbit, its distance, when at the farther extremity of its greater axis, is nearly double that of Uranus, the most distant of the planets. When nearest to the sun, its distance from him is about $\frac{6}{10}$ th parts of the earth's mean distance.

438. *A very remarkable comet* was seen in the end of 1680 and beginning of 1681. Its tail extended 70° , and was very brilliant. This comet, of all those which have been observed, approaches nearest to the sun. Descending with immense velocity in a path almost perpendicular to his surface, it proceeded until its distance from his centre was only about 540,000 miles. Sir Isaac Newton computed that, in consequence of so near an approach to the sun, it must have received a heat 2000 times greater than that of iron almost going into fusion; and that if it was equal in magnitude to our earth, and cooled in the same manner as terrestrial bodies, its heat would not be expended in less than 50,000 years.

439. *Three observations on comets* are recorded in history, agreeing in remarkable circumstances with the comet of 1680:—one in the 44th year before Christ; another in the consulate of Lampadius and Orestes, about the year of Christ 531; and the third in the reign of Henry I. of England, in the year 1106. These dates are nearly at equal distances of time, namely, 575 years; which is also the period between 1106 and 1681. Hence Dr. Halley conjectured that these might be successive appearances of one and the same comet, revolving about the sun in the period of about 575 years. If this conjecture is well founded, this comet may be expected again, after finishing the same period, about the year 2255.

440. *A comet remarkable for its beauty appeared in 1811.* The tail of this comet was composed of two diverging streams of faint light, slightly coloured, which made an angle of from 15° to 20° , and sometimes much more, and were bent outwards. The space between was comparatively obscure. When at its greatest length, the tail subtended an angle of at least 16° ; and was then computed to extend about 23,000,000 miles in length.

441. *Besides Dr. Halley's comet there are two others* whose returns have been observed, and the elements of their orbits determined, with such certainty, as to enable astronomers to predict their re-appearance. One of these was recognised for the first time in 1819 as a periodic comet. M. Encke, a German astronomer, has determined the time of its revolution about the sun to be three years and three months nearly. The other was last seen in 1825. Its periodic time was determined by M. Biela, a Bohemian astronomer, to be six years and three quarters. Altogether, then, there are only three comets whose periods are certainly known.

442. *Danger from comets.* As the comets traverse the planetary regions in all directions, it is natural to enquire whether there is not a possibility that some one of them may approach so near to the earth as greatly to disturb its motion, or by an actual contact to produce the most disastrous effects. Upon this subject there is no reasonable ground for fear. If it is not absolutely impossible that a comet may come in contact with the earth, the probabilities against such an event happening are as millions to one. Among bodies so small in comparison with the immense space in which they move; and moving with all velocities, and in orbits that are inclined in all directions, and are of all dimensions, how small must be the probability that any two shall come in contact! Small, however, as this probability is for any one age, if we take into account a long series of ages, the probability may be greatly increased.

443. *If we suppose the earth actually to receive such a shock,* it is easy to imagine the calamitous consequences which must follow. The axis and motion of rotation being changed, the waters of the ocean would leave their ancient position, and would be precipitated towards the new equator. A great part of the human race, and of the lower animals, would be drowned by this universal deluge, or destroyed by the violent shock impressed on the terrestrial globe. Whole species of animals might be annihilated. All the monuments of human industry and invention would be overthrown. In such a catastrophe we find, too, a cause adequate to account for the ocean having overflowed lofty mountains, on which it has left incontestible evidence of its presence; and to explain how the animals and plants of the south may have existed in the climates of the north, where we find the remains and impressions of them. Lastly, such an event accounts for the recentness of the moral world, the monuments of which go back scarcely 3000 years. The human race, reduced to a small number of individuals, and to the most miserable condition, would for a long time be mainly occupied in providing for their preservation, amidst the wreck which surrounded them, and would lose all remembrance of arts and sciences; and when, by the progress of civilisation, they at length became sensible of the want of these, they would find it necessary to recommence, as if man had been newly placed upon the earth.

444. *It seems impossible to contemplate the picture of calamity here drawn,* without being forcibly struck with this singular coincidence;—that if we suppose the period of the comet of 1680 (which in that year made a considerably near approach to the earth's orbit) to be $575\frac{1}{2}$ years; and count back, from the year 1680, seven revolutions, or a period of 4028 years, we reach the year 2349 before Christ,—the year of the deluge, as fixed by chronologers.

445. If we take into consideration the great velocity with which the comets move in approaching to and receding from the sun, it is evident that *the mere approximation of a comet to the terrestrial orbit, would be productive of little or no effect.* Accordingly, though a comet is said to have eclipsed the moon, in which case it must have been very near the earth, no sensible effect was produced.

CHAP. XV.

LAW OF UNIVERSAL GRAVITATION.

446. *Having now taken a brief view of the planetary motions, and pointed out generally their laws, we may next inquire whether from these any general principle can be deduced to which the motions regulated by them may be referred as to their cause.*

447. *The motions of the heavenly bodies have been variously accounted for.* We have already adverted to the rude mechanism of deferent and epicyclic spheres, by which some of the ancient philosophers attempted to explain the celestial motions. This doctrine originated with Eudoxus and Callipus. But a more sensible attempt was made by Cleanthes, another philosopher of Greece, who, from observing that bodies are easily carried round by whirlpools or vortices of water, imagined that the celestial spaces are filled with an ethereal fluid, which is in continual motion round the earth, and that it carried the sun and planets round with it. Though this hypothesis affords no real explanation of the phenomena, it was revived in modern times, and maintained by two of the most eminent mathematicians and philosophers in Europe, namely, by Des Cartes and Leibnitz, and for a long time met with general acquiescence. But a much nearer approximation to right conceptions on this subject was made by many philosophers, both of ancient and modern times, who supposed that the planets were deflected from uniform rectilineal motions, by forces similar to what we observe in the motions of magnetical and electrical bodies, or in the motion of common heavy bodies; where one body seems to influence the motion of another at a distance from it, without any intervening impulsion. Fermat was the first who suggested that the weight of a body is the sum of the tendencies of each particle of matter in the body to every particle of the earth. Kepler made another approximation to the truth when he said, that if there were two bodies placed out of the reach of all external forces, and at perfect liberty to move, they would approach each other with velocities inversely proportional to their quantities of matter; when he asserted that the earth and the moon mutually attract each other, and are prevented from meeting by their revolution round their common centre of attraction; and when he attributed the tides to the attractive influence of the moon in heaping up the waters immediately under her.

448. *But Dr. Hooke made the most precise surmise to this purpose.* At a meeting of the Royal Society, May 3. 1668, he expressed himself in the following manner: — “I will explain a system of the world very different from any yet received, and it is founded on the three following propositions: —

“1. That all the heavenly bodies have not only a gravitation of their parts to their own proper centres, but that they also mutually attract each other within their spheres of action.

“2. That all bodies having a simple motion will continue to move in a straight line unless continually deflected from it, by some extraneous force causing them to describe a circle, an ellipse, or some other curve.

“3. That this attraction is so much the greater as the bodies are nearer. As to the proportion in which these forces diminish by an increase of distance, I own I have not yet discovered it, although I have made some experiments to that purpose. I leave this to others who have time and knowledge sufficient for the task.”

The truly philosophical views stated in these propositions relatively to the celestial motions were illustrated by a very pretty experiment, which Hooke had some time before exhibited to the Society. A ball, suspended by a long thread from the ceiling, was made to swing round another ball laid on a table immediately below the point of suspension. When the impulse given to the pendulum was very nicely adjusted to its deviation from the perpendicular, it described a perfect circle round the ball on the table; but when the impulse was very great or very little, it described an ellipse having the other ball in its centre. The force, under the influence of which this circular or elliptic motion was produced, Hooke showed to be a deflecting force, proportional to the distance from the other ball. But he added, that although this illustrated the planetary motions in some degree, yet it was not suitable to their case; for the planets describe ellipses, having the sun not in their centre but in their focus, so that they are not retained in their orbits by a force proportional to the distance from the sun.

449. *Thus we see that certain points of resemblance between the motions of the planets and*

the motions of magnets and heavy bodies, had attracted the attention of many philosophers; but these observers failed to deduce from the principles which they so dimly perceived any satisfactory conclusion.

450. *At length the powerful genius of Sir Isaac Newton* was directed to the subject, and by his penetrating sagacity the law of universal gravitation was brought fully into view, and successfully applied to explain the celestial phenomena. He had retired from Cambridge to the country on account of the plague, and while walking in his garden he was led to meditate on the planetary motions, and on the nature of that central force which retains the planets in their orbits. The thought happily occurred to him that the same force, or some modification of the same force, which causes a heavy body to descend to the earth, might extend to the moon, and might retain that body in its orbit by deflecting it from the rectilinear path. However plausible this conjecture might appear, the mind of Newton was too deeply imbued with the true spirit of philosophy to adopt it as the groundwork of a theory, unless it could be shown by calculation to be coincident with fact. But before it could be brought to this test, it was necessary that he should form some conditional hypothesis respecting the modification of the force as the distance increased, and also that he should know nearly the magnitude of the earth. The hypothesis which he assumed with regard to the modification of the force according to the increase of the distance was correct; namely, that the force decreases as the square of the distance increases. But he made a false estimation of the bulk of the earth; so that his calculations showed that his conjecture did not agree with the phenomenon: he accordingly abandoned it. A few years afterwards he was induced, however, to renew his calculations, having in the interval obtained more correct *data*, in consequence of the measurement of a degree in France by Picard. The attempt now succeeded; and it is said that, as his calculations drew to a close, he became so agitated that he was obliged to request a friend to finish them. His former conjecture was found to agree with the phenomena with the utmost precision; and in exploring the grand scene which was now laid open before him, he was led to an explanation of the system of the world, consisting simply in an accurate narration of facts, and such an arrangement of them as showed their mutual dependence, and, at the same time, their reference to one great fact of which they were all necessary consequences.

451. *We are now to explain briefly the theory of gravitation*; but our account of it must of course be very limited.

452. *There is no phenomenon in nature more familiar to us than motion*; and although it be greatly diversified, according to the causes by which it is produced, yet all motions are subject to the three following laws:—

1st LAW. Every body continues in a state of rest, or of uniform rectilinear motion, unless affected by some mechanical force.

2d LAW. Every change of motion is proportional to the force impressed, and is made in the direction of that force.

3d LAW. Every action is accompanied by an equal and contrary re-action.

It is a consequence of the first two laws, that if a body or particle of matter be subjected at the same time to the action of two moving forces, each of which would separately cause it to describe the side of a parallelogram uniformly in a given time, the body will describe the diagonal uniformly in the same time. By these very simple laws, the result of experience, and by the principles of geometry, Newton established the sublime doctrines of the planetary motions.

453. *It will not be expected that we should enter at any considerable length into the recondite doctrines of physical astronomy.* This subject requires for its full discussion ample space, and all the resources of the higher mathematics: the mere elements of geometry, however, are sufficient to indicate generally some of the fundamental principles.

Let us suppose that S (fig. 34.) is a fixed point, and that a body moves in the direction AB with an uniform velocity, at such a rate, that if not disturbed by any external cause, it would move from B to *b* in a second of time. Let us also suppose that when the body arrives at B, it receives an impulse in the direction BS, and of such intensity, that, if acting alone, it would cause the body to move uniformly from B to H in a second. Complete the parallelogram HB*b*C, and draw the diagonal BC: the impulse at B, combined with the tendency to continue

its motion in the line Bb will cause the body to move along the diagonal BC ; so that at the end of a second it will actually be at the point C ; and if no external cause acted on the body, by the first law, it would continue to move uniformly ever after in the direction Bc ; so that in the next second it would describe a line Cc , equal to BC . But now suppose that the body, when at C , receives a second impulse in the direction CS , by which it would be carried uniformly from C to I in a second; then, completing the parallelogram $DICc$, the actual path of the body will be the diagonal CD , which will be uniformly described in a second; and if undisturbed, the motion would be continued uniformly in the straight line Cd , the distance Dd described in the next second being equal to CD . A third impulse at D , in the direction DS , such as would carry the body uniformly from D to K in a second of time, would, when combined with the tendency to move in the direction Dd , produce a motion along DE , the diagonal of the parallelogram $EKDd$, and a fourth impulse in the direction ES , would, when combined with the motion in the direction Ee , produce a motion along the diagonal EF , and so on. In this way, by successive instantaneous impulses, a body may be made to describe the path $ABCDEF$, &c., which will be all in one plane.

454. Since the lines AB , Bb are equal, the triangles ASB , BSb are equal; but because Cb is parallel to SB , the triangle BSb is equal to the triangle BSC ; therefore the triangle BSC is equal to ASB . In like manner, it may be proved that CSD is equal to BSC , and DSE to CSD , and so on: thus it appears that the triangles ASB , BSC , CSD , DSE , &c. are all equal. If we suppose a straight line to be drawn from the moving body to the fixed point S , and to be continually carried along with it, it is evident that this line will pass over or generate the equal areas ASB , BSC , CSD , DSE , &c. in equal intervals of time: it is also evident that the shorter the interval between the impulses communicated to the moving body, the greater will be the number of sides of the figure formed by the diagonals of the parallelograms, and the nearer will the line composed of these diagonals approach to a curve. If we suppose, therefore, that the body is urged towards F by a force acting, not at intervals, but incessantly, the body will move in that curve to which, as its limit, the line, composed of the diagonals continually approaches, while the line drawn from the moving body AS , or *radius vector*, will continue to describe areas proportional to the times.

455. The force which urges the body towards S , is called a CENTRIPETAL FORCE. If the action of that force were to cease, the body would proceed in a straight line, — a tangent to its curvilinear path. The tendency of the body to proceed in the direction of the tangent, is called its CENTRIFUGAL FORCE.

456. From the important conclusion to which we have now been led, we may infer, conversely, that if a body revolve in a curvilinear path about a point, and if the radius vector drawn from that point describe round it areas proportional to the times, the body is deflected from the rectilinear path by a force directed to that point. Now, this is exactly the case of the planets, both primary and secondary. The former describe curvilinear orbits round the sun; and, according to the second of Kepler's laws, the radius vector describes areas proportional to the times. Hence we may infer, that each is retained in its orbit by a centripetal force directed towards the sun; and that this force is counteracted by a centrifugal force generated by the planet's motion in its orbit. In like manner, each secondary planet revolves about its primary, the areas described by the radius vector following the same law; so that the secondary must be acted upon by a centripetal force directed towards the primary planet.

457. The next thing to be determined is the law of the centripetal force when a body moves in an elliptic orbit, the force being directed towards one of the foci. First, let us suppose a body to revolve in the circumference of a circle ADC (fig. 35.), about any point S , as the centre of its motion, and let us inquire into the law of the centripetal force in that case. Draw the chord ASC , and let AD be so small an arc, that it may be considered coincident with its chord. Draw DE parallel to the tangent AB , and join CD . Then AD will measure the velocity of the body in its orbit at the point A , and AE the space over which the centripetal force directed towards S , if acting alone, would cause the body to move in the time in which it moves from A to D . Put v to denote the velocity, and f the centripetal force. Since the triangles ADC , AED , are equiangular and similar, we have $AC : AD = AD : AE$; that is,

$$AC : v = v : f : \text{therefore } f = \frac{v^2}{AC}.$$

458. Next, let APB (fig. 36.) be the elliptic orbit of a planet, S the focus in which the sun is placed, A the point at which the planet is at its greatest distance from the sun, and P any other point in its orbit. Join PS ; draw the tangent PD , and draw SD perpendicular to PD . Let v and v' denote the velocities of the planet at A and P respectively; and c and c' the chords of the equicurve circles at A and P which pass through the point S , and let f be the deflecting force at A , and f' the deflecting force at P . Then from what we have proved respecting a body moving in the circumference of a circle

round any point F as the centre of its motion, we have $f : f' = \frac{v^2}{c} : \frac{v'^2}{c'} = v^2 c' : v'^2 c$. But since the small arcs which represent the velocities at A and P must be supposed to be described in equal times, the corresponding areas described by the radius vector will also be equal. Hence it is not difficult to see that $v \times AS = v' \times SD$, and $v : v' = SD : SA$. We obtain, therefore,

$$f : f' = SD^2 \times c' : SA^2 \times c.$$

Draw PE perpendicular to the tangent PD , meeting the axis in E , and draw EG perpendicular to PE , and EH perpendicular to PF . From the properties of the ellipse, PH is equal to half the principal parameter, and consequently to half of c , the chord of the circle, of equal curvature at A , which passes through S . Also PG is half of c' , the chord of the equicurve circle at P , which passes through S . Therefore,

$$f : f' = 2SD^2 \times PG : 2SA^2 \times PH.$$

$$= SD^2 \times PG : SA^2 \times PH.$$

Now, from the similar triangles GPE , EPH , we have $GP : PE = PE : PH$; hence $GP : PH = GP^2 : PE^2$. But the triangles GPE , PSD being also similar, $GP^2 : PE^2 = PS^2 : SD^2$; therefore, $GP : PH = PS^2 : SD^2$; and $PS^2 \times PH = SD^2 \times GP$: and since it was shown that $f : f' = SD^2 \times PG : SA^2 \times PH$, wherefore $f : f' = PG^2 \times PH : SA^2 \times PH$; or leaving the common factor PH out of the two consequents we have

$$f : f' = PS^2 : SA^2.$$

Thus we have arrived at this important conclusion; that the force by which the planets revolve round the sun in elliptical orbits, the sun being in one of the foci, and the radius vector describing areas proportional to the times, is always inversely as the squares of the distances.

459. There remains yet another point to be determined respecting the forces which retain the different planets in their orbits; namely, whether there is any analogy between them. From Kepler's third law, we know that the squares of the periodical times of any two of the planets are proportional to the cubes of their mean distances from the sun. This law is independent of the eccentricities of the orbits; and the same relation would subsist between the mean distances and the periodic times, though the eccentricities were to become infinitely

small; or, what is the same thing, the orbits were to become circles. Let us then suppose the planets to move with uniform velocities in circular orbits, having the sun in the centre. This supposition differs very little from the truth. Put v, v' to denote the velocities of two of the planets, r, r' the radii of their orbits, t, t' their periodic times, and f, f' the forces by which they are retained in their orbits. From what we have already shown respecting a body moving in a circle round any point as the centre of its motion, we have $f = \frac{v^2}{2r}$ and $f' = \frac{v'^2}{2r'}$, therefore $f : f' = \frac{v^2}{r} : \frac{v'^2}{r'}$. But since the circumferences of circles are to one another as their radii, and the velocity or the space passed over by the planet in the unit of time is equal to the circumference of its orbit, divided by the periodic time expressed in that unit, it is evident that $v : v' = \frac{r}{t} : \frac{r'}{t'}$; hence $\frac{v^2}{r} : \frac{v'^2}{r'} = \frac{r}{t^2} : \frac{r'}{t'^2}$; or, since $t^2 : t'^2 = r^3 : r'^3$, $\frac{v^2}{r} : \frac{v'^2}{r'} = \frac{r}{r^3} : \frac{r'}{r'^3} = \frac{1}{r^2} : \frac{1}{r'^2} = r'^2 : r^2$. Wherefore we obtain $f : f' = r'^2 : r^2$.

460. *This result shows that the forces which, acting on two planets, would cause them to describe circular orbits, agreeing with Kepler's third law, are inversely as the squares of the distances.* Hence we may infer the sameness of the force which retains the planets in their respective orbits; since it varies from orbit to orbit, according to the very same law which regulates its intensity at different distances in the same orbit. This conclusion is fully established by the fact, that the force which acts upon the comets during their descent to the sun, varies exactly according to the law which we have now assigned as the law of the planetary force. The comet of 1759, which was predicted by Dr. Halley, came from regions far beyond the most distant of the known planets, and approached nearer to the sun than Venus; and when it arrived at the same distance from the sun as any of the planets, its deflection from the rectilinear course by the action of the centripetal force, was the very same as that of the planet. We may, therefore, conclude, that it is one and the same force which deflects all the planets as well as the comets.

461. *From what has now been shown, it is evident that if all the planets were placed at the same distance from the sun, they would all be deflected equally by the centripetal force independently of the quantity of matter in each.* Hence it follows that, at equal distances, the centripetal force must act equally on every particle of matter of which the planets are composed; so that if one planet contain exactly double the quantity of matter that another planet contains, and if both are placed at exactly the same distance from the sun, the former will receive a double impulse. We may infer, therefore, that another law of the force which retains the planets in their orbits is, that, at equal distances, it is proportional to the mass on which it acts: and that if two bodies act on the same particle of matter, the forces which they exert are proportional to their masses. The force may be supposed to be produced either by a cause residing in the body which is placed in the centre of motion, or by a cause residing in the revolving body. In the former point of view, it is called a force of ATTRACTION; in the latter, a force of GRAVITATION. The truth is, however, that the cause of this force is absolutely unknown. We see only the effects produced, and from these we investigate the laws which connect them with each other, and the general principles on which they depend.

462. *Thus, from the facts discovered by Kepler respecting the planetary motion, we have shown that each planet has a tendency towards the sun, in consequence of which from a state of rest it would move towards him, acquiring at every instant an increase of velocity according to a fixed and determinate rule or law which applies alike to all the planets.* This tendency, if not counteracted, would bring the matter of the sun and planets into one mass. This, however, is prevented from taking place, in consequence of an impulse having been originally communicated to each planet, giving it a constant tendency to move in a straight line with an uniform velocity. The effects arising from these two tendencies are so adjusted, as to produce elliptic orbits. But the law which regulates the effects arising from the tendency of the planets towards the sun remaining the same, such a velocity might have been communicated to each planet, by the original impulse which gave it its tendency to move uniformly in a straight line, as would have produced parabolic or hyperbolic orbits. In a circular orbit, if the centre of motion coincide with the centre of the orbit, the velocity of a planet is uniform, and of such rapidity as at every point to produce a tendency to move in a tangent to the orbit, exactly sufficient to counterbalance the tendency to move towards the centre of the orbit. If the orbit be elliptical, and one of the foci the centre of motion, the motion of the planet is variable, and its tendency to move uniformly in a tangent to the orbit sometimes exceeds, and at other times falls short of, that which would be necessary to cause it to revolve in a circle at the same distance from the centre of motion.

463. *Let A D B E be the elliptic orbit of a planet revolving about the sun, which is supposed to be placed in the focus S. Suppose the planet to set out from A in the direction A P, A being the point of its greatest distance from the sun. At A the direction of the planet's motion is at right angles to the radius vector, and if the velocity were such as to produce a tendency to move in the direction of the tangent A G, exactly equivalent to the tendency of the planet to move towards the sun, the planet would revolve in a circle of which S is the centre, and S A the radius. But the velocity being supposed less, the path of the planet will fall within the circle, and the angle S P H contained between the radius vector and the tangent P H, which shows the direction of the planet's motion, changes from a right*

angle to an acute angle. The tendency of the planet towards the sun is now exerted partly

in accelerating its velocity in its orbit, and partly incurvating its path. While the planet describes the quadrant A P D, its velocity is always less than that which would produce a circular motion; until it is at the point D, and then the velocity is precisely what would be sufficient for a circular motion about S, if its direction were perpendicular to the radius vector: the direction, however, being oblique, the planet is brought still nearer to S. The tendency towards the sun is, in a great measure, still exerted in accelerating the motion, and as soon as the planet passes D, its velocity becomes greater than what might produce a circular motion about S. The angle S D K is, therefore, the least angle which the radius vector makes with the direction of the

planet's motion, and from the moment when the planet passes the point D, that angle begins to increase; and the effect of this is to cause the tendency of the planet towards the sun to be principally exerted in incurvating the orbit. Its influence in accelerating the planet's motion, though it still exists, is gradually diminished, until the planet arrives at the point B, where it ceases altogether, in consequence of the radius vector being at right angles to the tangent B L.

464. *As the velocity of the planet at B is greater than what is sufficient to produce a motion in a circle of which the radius is S B, the path of the planet falls wholly without that circle; and, consequently, it is now receding from the sun. The angle which the radius vector makes with the direction of its motion becoming obtuse, the tendency of the planet towards the sun is now partly employed in retarding its motion, so that its velocity is diminished. The angle contained between the radius vector and the direction of the planet's motion increases while the planet is moving from B to E, and decreases from E to A, when it becomes a right angle, as it had formerly decreased from A to D, and increased from D to B. The velocity of the planet in its orbit must, therefore, decrease from B to A, as it had formerly increased from A to B; at the point E it will be equal to what it was at D, and from E to A, the influence of the planet's tendency towards the sun to diminish its velocity will become less and less, until when the planet has arrived at A, it will cease altogether. The velocity is then the same as at first, and the motion goes on in this way for ever.*

465. *Whatever has now been deduced from Kepler's Laws respecting the orbits of the primary planets, and the law of the force by which they are described, will apply equally to the orbits of the secondary planets: for in each of these little systems, there is the same analogy between the periodic times and the distances, which takes place in the general system; the figure of the orbits is also elliptic, and the areas described by the radius vector is proportional to the times. We may legitimately conclude, therefore, that the satellites revolving about any planet, are retained in their orbits by a force inversely proportional to the squares of their distances from their primary planet; so that all the celestial motions are produced by forces regulated by this general law.*

466. *The force which keeps the Moon in her orbit is, then, the attraction of the earth, or her gravitation towards the earth. But we find that the earth attracts all the bodies near its surface by a force which is proportional to the mass of the body attracted. Whatever be the weight of a body, it falls to the earth from the same height in the same time, and with the same velocity. Thus, if the resistance of the atmosphere be removed, it is found by experiment that the lightest feather falls to the earth, from a given height, in the very same time, and with the very same velocity, as a stone, however great its weight. Let us enquire whether the force which retains the moon in its orbit may not be identified with this attractive force which causes the descent of heavy bodies to the surface of the earth.*

467. *We may without great error suppose the lunar orbit to be circular, and its semidiameter to be equal to*

sixty semidiameters of the earth. Let it be represented by the circle C M A, the earth being supposed to be placed at the centre E; and let M C be the small portion of the orbit which the moon describes in a second of time. Draw M B a tangent to the orbit at M: draw also C D parallel to M B, and C B parallel to M A, the diameter of the orbit. The arch M C may be regarded as coincident with its chord; therefore, joining A C, it is evident that in the right angled triangle A C M we have $AM : MC = MC : MD$. Hence, since A M and M C are known, M D or B C, the deflection of the moon from the tangent, in a second by the attraction of the earth, may be found.

468. *The moon describes her orbit round the earth in about $27^d 7^h 43^m$, or 2,360,580 seconds; the circumference of her orbit is about 60 times the circumference of the earth, that is, if we reckon $69\frac{1}{2}$ English miles to a degree, 7,926,336,000 feet; therefore the length of the arc M C, which the moon describes in a second, will be found nearly equal to 3358 feet. Again, A M, the diameter of the moon's orbit, is about 2,523,031,140 feet. Hence we obtain M D equal to 00447 feet nearly. This small fractional part of a foot is the space which a body, placed at the distance of the moon, and falling from a state of rest by the action of the force which retains the moon in her orbit, would pass over in the first second of time. Observing, now, that this force*

increases as the squares of the distances decrease, we may determine the space which a body at the surface

of the earth (or at the distance of one semidiameter from the earth's centre), and falling from a state of rest, would pass over in the first second of time, if urged by the same force. For, since the moon's distance from the earth is equal to about sixty times the semidiameter of the earth, we have $1^2 : 60^2 = .00447$: the space required, which is found to be 16.09 feet. Now, this is exactly the space which a body, falling from rest by its own weight, is found by experiment to pass over in the first second of time. Hence we may infer, that *the moon is retained in its orbit by the very same force which produces pressure in a body supported, or causes a body when unsupported to fall to the ground.*

469. *Though the attraction of the earth on bodies near its surface is only a particular case of a general principle, which produces all the planetary motions, the effects are, to appearance, considerably modified. At all the heights to which we are able to ascend above the general surface of the earth, or to which we can project a body, the force of gravity acts, as to sense, uniformly: it also acts in the direction of straight lines, perpendicular to the horizon, and therefore parallel to one another, for the greatest range that can be given to a projectile. Hence the phenomena, which depend on the force diminishing in intensity, as the square of the distance increases, and on its emanating in the direction of straight lines drawn to the centre of the attracting sphere, become imperceptible. In consequence of the comparatively small velocity with which human power can project a body, its path always meets the earth, and its motion terminates. But if the whole matter of the earth were collected into a point at the centre, a body projected from a point 4000 miles distant from the centre, and with such a velocity as human power can communicate, would be acted upon by the same forces, with a body similarly projected from the surface of the earth. But on the supposition now made, the body would meet with no obstacle, but would approach within a certain distance of the centre, and would then recede from it until it reached another limit, when it would again approach, and go on in this manner, approaching and receding alternately, for ever. The path of the body would be an ellipse, resembling in figure the orbit of a comet. The extreme portions of the path would, as to sense, be portions of a parabola. Hence it is usually laid down as a law regulating the motion of projectiles, that if a heavy body be projected in a straight line, not perpendicular to the horizon, it will describe a parabola situated in the vertical plane passing through that straight line, and having its axis perpendicular to the horizon. This physical truth was first discovered by Galileo.*

470. *The force of gravity near the surface of the earth being uniform in its action, it is found that the motion which it produces corresponds in all its circumstances with that which mathematical reasoning shows should result from the action of a constant force. The spaces through which the body falls are proportional to the squares of the times, and the velocity is proportional to the time during which the body has been falling.*

471. From the third law of Kepler, it is not difficult to see that *the periodic time of a planet in its orbit is determined entirely by the mean distance, that is, half the transverse axis; and is not at all affected by the increase or decrease of the conjugate axis. By supposing, then, the conjugate axis to be continually diminished, we are led to this conclusion, that the time in which a body would descend to the sun, if allowed to fall from a state of rest at any distance from him, is equal to half the time of revolution in an ellipse the semitransverse axis of which is half of that distance. Let T be the time of revolution of a planet at any distance, and t the time of revolution at half that distance; then, by the third law of Kepler, $T^2 : t^2 = 2^3 : 1^3$; hence we*

have $t = \frac{T}{\sqrt{8}}$, and $\frac{1}{2}t = \frac{T}{\sqrt{32}}$. But $\frac{1}{2}t$ is the time in which a body would fall from the distance corresponding to T. Hence *the time in which a planet would fall to the sun by the action of the centripetal force is equal to the periodic time divided by $\sqrt{32}$; or (what amounts to the same thing) to the periodic time multiplied by 0.176776, the reciprocal of the square root of 32. By this general rule, the times in which the different planets would reach the sun, if the action of their centrifugal should entirely cease at the moment when they are at their mean distances, are as follow:*

	Days.	Hrs.		Days.	Hrs.
Mercury in	15	13	Juno	354	19
Venus	39	17	Vesta	205	0
The Earth	64	13	Jupiter	765	19
Mars	121	10	Saturn	1901	0
Ceres	297	6	Georgium Sidus	5425	0
Pallas	301	4	The Moon would fall to the Earth in	4	20

472. *The principle in the Newtonian philosophy, that the effects produced by the attraction of a body depend very much upon the quantity of matter which it contains, furnishes the means of resolving a problem which at first sight may appear of such difficulty as to transcend the powers of the human mind; namely, to determine the quantity of matter in the sun and planets. Let f and f' denote the forces by which two bodies revolve in circular orbits round two central bodies, of which the masses are denoted by m and m'. Let r and r' be the radii of the orbits, and t and t' the periodic times. From what we have already proved with regard to a force that retains a body in a circular orbit, we have*

$f : f' = \frac{r}{t^2} : \frac{r'}{t'^2}$. But we have also $f : f' = \frac{m}{r^2} : \frac{m'}{r'^2}$; therefore, $\frac{m}{r^2} : \frac{m'}{r'^2} = \frac{r}{t^2} : \frac{r'}{t'^2}$; and consequently, $m : m' = \frac{r^3}{t^2} : \frac{r'^3}{t'^2}$.

Thus it appears that *the masses of matter in the bodies which compose the solar system are directly as the cubes of the mean distances of any bodies which revolve round them, and inversely as the squares of the times in which the revolutions are performed. By means of this principle, the masses of the sun and of the planets which have satellites may be compared with one another. With regard to the planets which have no satellites, the quantity of matter contained in them can only be guessed from the effects they produce on the motions of the other planets. The quantity of matter in the moon can, however, be determined*

with greater certainty, by comparing together the influence of the sun and moon in producing the tides and the precession of the equinoxes. Hence we learn, that the matter in the moon is about $\frac{1}{70}$ of the matter in the earth.

The following table exhibits the masses of the planets, that of the sun being considered as unity :

TABLE.

Mercury	-	-	-	2025810	Jupiter	-	-	-	107015
Venus	-	-	-	465871	Saturn	-	-	-	3512
The Earth	-	-	-	334936	Uranus	-	-	-	17918
Mars	-	-	-	2546326					

If we add together the numbers given in this table, it will be found that the whole matter in all the planets is not one-six-hundredth part of the matter in the sun.

473. *Knowing the masses of the planets and their diameters*, we can determine the force of gravity at their surfaces; for, supposing them to be spherical bodies, and to have no rotation on their axes, the forces with which a body placed on their surfaces gravitates to them will be *proportional to their masses, divided by the squares of their diameters*.

474. *From the masses of Jupiter and the earth*, La Place calculates that if we suppose them to have no rotation, a body which at the earth's equator weighs one pound would, if carried to the equator of Jupiter, weigh 2.509 pounds, supposing the weights to be measured by the pressures exerted in the two situations. If the centrifugal force produced by the rotation of the planets be taken into account, however, this weight must be diminished by about one-ninth part. The same body would weigh about 27.65 pounds at the surface of the sun. Hence it follows that a heavy body would there descend about 425 feet in the first second of time.

475. *We have hitherto attended chiefly to the action of the central body upon that which revolves round it*; but, in reality, the action is mutual. The planets attract the sun in the same manner as the sun attracts the planets; and the same action and re-action have place among the primary planets and their satellites. Indeed, the gravitation of all the great bodies of the system towards one another, appears only to be a consequence of a similar action between every particle of matter and every other particle of matter. This great fact, to which all the celestial phenomena are ultimately to be referred — *that the particles of matter mutually attract each other by a force varying inversely as the squares of the distances* — is commonly called the principle of UNIVERSAL GRAVITATION.

476. *The mutual attraction of the bodies composing the planetary system gives rise to a train of consequences which it has required the utmost efforts of human ingenuity to unfold*. We have already remarked that the planetary motions are liable to a variety of irregularities with which accurate observation has made us acquainted. Now, here we see the cause to which all these irregularities are to be referred. If the sun were fixed immovable in the centre, and only one planet revolving round him, then the path of that planet would be an ellipse, from which there would not be the least deviation; and that focus which is the centre of motion would coincide with the centre of the sun, supposing that body to be spherical and composed of matter of uniform density. But since the planet attracts the sun as well as the sun attracts the planet, with a force directly proportional to the mass and inversely proportional to the square of the distance, it follows that the sun must also move in an elliptic orbit round that point of which the condition is in no way disturbed by the mutual action of the revolving bodies, namely, their CENTRE OF GRAVITY. It is with this point that the focus of the orbit of the planet, and that of the solar orbit, would coincide, and about which the radius vector of each would describe areas proportional to the times. In reference to this point also, the squares of the periodic times would be proportional to the cubes of the distances.

477. *If we now suppose two or more planets to revolve about the sun*, it is evident that the motions of all would be disturbed by their mutual gravitation. The immense magnitude of the sun compared with that of any of the planets, or of all the planets taken together, might, however, give to his attraction such a preponderance as would preserve all the planetary orbits nearly elliptical; while his own orbit would become a more complicated curve, but such as to furnish a centrifugal force in respect of each planet, just able to counterbalance the gravitation towards it. The centre of gravity of the whole system would be a point to which all their motions are to be referred. Now this is actually the case of the planetary system. Accurate observation proves that the sun is not at rest in the centre, though his motion is very small. His centre is never distant from the centre of gravity of the system so much as his own diameter; and hence the orbit which he describes must be very inconsiderable, when compared with the orbits of the planets. With regard to those planets which are accompanied by satellites, it is not the centre of the primary which traces the elliptic orbit round the sun, but the common centre of gravity of the primary planet and secondary planets which revolve round it.

478. *The perturbations which the mutual attraction of the planets produce in each other's motions are divided into two classes. The one class affect the figure and position of the elliptic orbits, and increase with extreme slowness: these are called SECULAR INEQUALITIES. The other class depend on the mutual situation of the different planets, and acquire the same amount whenever the same relative positions occur: these are called PERIODIC INEQUALITIES. Both these classes of inequalities have been demonstrated to be periodical; that is, they increase only to a certain extent, and then decrease. Amidst all the changes which arise from the mutual actions of the heavenly bodies, there are two things which remain perpetually the same; namely, the greater axis of the orbit which the planet describes, and its periodic time. Thus the permanency of the planetary system is secured.*

479. *To subject to calculation the perturbations of the system requires the solution of the following problem: three bodies of given magnitudes, as the sun, the earth, and the moon, being projected into space with given velocities, and in given directions, and attracting each other according to a given law, namely, inversely as the squares of their distances from each other, and directly as their masses; it is required to determine the nature of the curve, that one of them, as the moon, describes about one of the other two, as the earth. This is the celebrated PROBLEM OF THE THREE BODIES, stated in all its generality, but under this aspect its solution is beyond the reach of the most refined methods of analysis which the mathematical sciences in their present state furnish. In its application to the purposes of physical astronomy, there are certain conditions which render the problem less difficult; viz. 1. That the sun greatly exceeds in magnitude the other two bodies, and is nearly at rest. 2. Its distance from the earth and moon is so great, that it may be considered the same for both. This condition fails, however, in reference to the action of the primary planets on one another, a circumstance which augments the difficulty of investigating the perturbations arising from their mutual gravitation. 3. The planetary orbits are nearly elliptical, and the aberrations from the ellipse in reference to each, are all that is required. Even with these limitations the problem is sufficiently difficult, and has engaged the attention, and exercised the skill of the most celebrated mathematicians of modern times.*

480. *The general view which we have now given of the planetary disturbances is all that our present object requires. We shall only, therefore, farther advert to the explanation which the theory of gravitation affords of the figure of the earth, and of the tides.*

CHAP. XVI.

FIGURE AND CONSTITUTION OF THE EARTH DEDUCED FROM THE THEORY OF GRAVITATION.

481. In the beginning (Chap. III.) we proved that the earth must be nearly spherical, in order to account for the general phenomena which we constantly observe. As soon, however, as the general *law of gravitation* was discovered, it was a necessary consequence that the earth could not be a perfect sphere, but must rather be an oblate spheroid flattened at the poles, and swelled out at the equator, and this inference is independent of all actual measurement, but may be confirmed by observation, and in fact has been so, as will be afterwards fully proved. This deviation from the spherical figure is to be attributed to the influence of the centrifugal force, arising from the earth's diurnal rotation, in diminishing the force of gravity from the pole towards the equator, where the centrifugal force, in reference to the surface, is the greatest possible. This tendency which every particle of matter in the earth has to fly off in the direction of a tangent to the circle in which the particle is carried by the earth's motion of rotation would be increased if that motion were to be accelerated: and may be conceived to be increased to such power as not only to overcome the force of gravity, but also the force by which the particles adhere to one another, and so to cause the earth to separate into fragments. Suppose a small satellite to revolve round the earth close to its surface at the equator; its periodic time may be deduced from that of the moon, on the principle that the squares of their periodic times would be to one another as the cubes of their distances. For we have (since the moon's distance is about sixty times the semidiameter of the earth, and the time of her periodic revolution 39343 minutes,)

$$60^3 : 1^3 = 3,9343^2 : \text{sq. of the periodic time of the satellite.}$$

Hence we obtain the periodic time nearly equal to $84\frac{1}{2}$ minutes. If the earth revolved about its axis in $84\frac{1}{2}$ minutes while such a satellite described a circular orbit close to its surface, the satellite would therefore appear to be at rest on the surface, but would not in the least degree press upon it, because the force of gravity would be exactly counterbalanced by the centrifugal force produced by the motion of the satellite in its orbit. Now, all the objects on the surface at the equator would be in the very same circumstances with the satellite; for they actually describe circles in consequence of the earth's motion, and if the earth revolved in $84\frac{1}{2}$ minutes, their centrifugal force would become exactly equal to the

force of gravity; so that they would no longer have weight. If the earth's motion of rotation became still more rapid, they would fly off from the surface.

482. *At the equator a body describes a circle of which the circumference is about 132,105,600 feet in $23^{\text{h}} 56^{\text{m}}$ nearly: it must therefore describe an arc of about 1528 feet in a second of time. From what we have shown already respecting central forces, it is evident that, by dividing the square of this arc by the diameter of the earth, we shall find the deflection from the tangent in a second, which will be the measure of the centrifugal force. This deflection amounts to about $\frac{67}{100}$ of an inch, or $\frac{1}{288}$ of $16\frac{1}{2}$ feet, the space through which a body would fall in a second by the force of apparent gravity. The centrifugal force at the equator is therefore the $\frac{1}{288}$ part of the sensible weight of a body, or $\frac{1}{289}$ part of its real weight. Suppose, then, a body, when weighed at the equator by a spring steel-yard, to be found capable of drawing out the spring to the division 288: if that body were weighed at the pole, where the centrifugal force vanishes, it would draw out the spring to the division 289.*

483. *It admits of being demonstrated that, proceeding from the equator where the centrifugal force is the greatest toward either pole, where it vanishes, the diminution of gravity which it produces in different latitudes is directly proportional to the squares of the cosines of the latitude.*

484. *Such being the nature of the forces that act upon every particle of matter of which the earth is composed, the determination of its figure from physical principles involves the solution of the two following problems:—*

1. *What is the law according to which a particle will gravitate towards a solid of a given form and constitution, the particle being supposed situated either within or without the solid?*

2. *What figure will a mass of matter, either wholly or partly fluid, assume in consequence of the joint effect of the attraction of its particles (that attraction varying inversely as the squares of their distances), and a centrifugal force arising from the rotation of the mass about an axis?—Both these problems involve a great degree of difficulty; and the second is even more intricate than the first, in consequence of the reciprocal relations subsisting between the figure of the attracting body and the law of gravitation at its surface, which renders a knowledge of the one necessary to the determination of the other. Assuming that an homogeneous fluid of the same mean density with the earth has the figure of an oblate spheroid, and revolves on its axis in $23^{\text{h}} 56^{\text{m}} 4^{\text{s}}$ of solar time, it would be in equilibrium, if the axis of revolution were to the equatorial diameter in the proportion of 229 to 230. This is the figure which Newton ascribed to the earth; and though the assumption which he made of such a figure was certainly gratuitous, the result of his investigation is almost the same as later writers have obtained by a more rigorous as well as direct mode of reasoning than that which he employed. Again, it has been demonstrated by La Place, that a fluid and homogeneous mass, of the mean density of the earth, cannot remain in equilibrium and possess at the same time an elliptic figure, if the time of its rotation be less than $2^{\text{h}} 25^{\text{m}} 17^{\text{s}}$. If the time of revolution exceed this, there may always be two elliptic spheroids, and not more, in which the equilibrium may be maintained. In the case of the mass revolving in $23^{\text{h}} 56^{\text{m}} 4^{\text{s}}$, the one spheroid is that which has already been mentioned; the other is one in which the polar diameter is to the equatorial in the ratio of 1 to 681. The extreme flatness of this spheroid must render the force of gravity at the equator almost nothing; the fluid, therefore, would be so easily dissipated that this equilibrium can scarcely be regarded as stable.*

485. *Another conclusion on this subject, deduced by Clairault, is, that if the fluid mass, supposed to revolve on its axis, instead of being homogeneous, be composed of strata which increase in density towards the centre, in order to remain in equilibrium, it must still possess the figure of an elliptic spheroid, but the oblateness will be diminished.*

486. *The oblateness of the earth at its poles is a phenomenon which the measurements that have been made of arcs of the meridian have placed beyond all doubt; but there is still an uncertainty as to the exact quantity of the compression. The results obtained, however, render it highly probable that it is less than $\frac{1}{230}$ which Newton, proceeding on the supposition of a uniform density, assigned for the compression. Hence we may conclude, that if the earth is a spheroid of equilibrium, it is denser in the interior than at its surface. This inference has been verified by very accurate experiments made by the late Dr. Maskelyne on the sides of the mountain Schiehallien, in Perthshire. The object was to determine the derangement of the plummet by the vicinity of this lofty and solid mountain; and the results, obtained from observation made at two stations on the south and north sides of it, showed that the plummet deviated from the direction of gravity towards the mountain more than $7''$. The quantity of this change of direction gives the ratio of the attraction of the mountain to that of the whole earth, or to the force of gravity, equal to the ratio of 1 to 17804. But the bulk and figure of the mountain being also obtained by a trigonometrical survey, its mean density was found to be to the mean density of the earth nearly as 5 to 9. Thus it appears that the mean density of the earth is not much less than double the density of the rocks which compose the mountain Schiehallien; and these, again, seem considerably more dense than the mean of those which form the exterior crust of the earth.*

487. It may appear an objection to this mode of reasoning concerning the figure of the earth, that it is not evident how a centrifugal force should produce the same effect on a solid body, like the earth, that it does upon a fluid mass. But the fact that the earth has made an approximation to the spheroid of equilibrium, is an indication that either the entire mass was originally fluid, from whatever cause; or the repeated waste and reconsolidation of the parts near the surface has gradually produced the spheroidal figure. In either of these modes the power of cohesion, which in the solid body resists the effects of the centrifugal force, may have been overcome. However irregular a body, whose surface is composed of land and water, may be in its primitive form; by the process of constant waste, the more prominent parts are gradually worn down, and the matter which composed them is deposited in the lower parts which are occupied by the water: here it acquires a horizontal stratification; and having, by certain mineral operations, under the transforming hand of nature, been consolidated into stone, the water being removed, it may again form a part of the solid crust of the earth. In this manner the primitive irregular form will gradually disappear, and the surface in the course of ages acquire a position at right angles to the direction of gravity; so that, by the action of the centrifugal force, there will be a constant approximation made to the spheroid of equilibrium. The irregular distribution of the heterogeneous materials which compose this terraqueous globe may, perhaps, prevent the coincidence from ever being complete.

488. It admits of being demonstrated, that if the earth were a perfect sphere, and composed of matter of uniform density at equal distances from its centre, the action of the solar and lunar attraction upon it would be the same as if the whole terraqueous mass were condensed into a point at the centre. Hence the position of its axis would not, in that case, be in the least degree affected by its gravitation towards the sun and moon, but would remain parallel to itself while the earth performed its annual revolution. In consequence of the spheroidal figure, however, the earth may be considered as composed of a sphere of which the radius is half the polar axis, and of a quantity of redundant matter, which is distributed over it in such a manner as to swell out the equatorial regions. The action of the solar and lunar attraction on this redundant matter produces the precession of the equinoxes and the nutation of the earth's axis. The complete explanation of these phenomena affords one of the happiest illustrations of the Newtonian doctrine of attraction; but requires at the same time the aid of some of the most abstruse theories both in pure mathematics and mechanics.

CHAP. XVII.

THE TIDES.

489. The alternate rise and fall of the surface of the sea, or its flux and reflux, known by the name of the TIDES, is a phenomenon which has attracted the attention of mankind from the earliest periods. Herodotus and Diodorus Siculus take notice of the daily flux and reflux of the waters of the Red Sea or Arabian Gulf, the latter historian describing it as a great and rapid tide; but neither of these writers form any conjecture respecting its cause. Observation must soon have shown, that this periodical ebbing and flowing of the waters of the ocean had an intimate connection with the position of the sun and moon in the heavens; and, accordingly, we find that Pliny not only describes the phenomena of tides, but expressly attributes them to the action of these luminaries.

490. It was not, however, until Newton applied the principle of universal gravitation to explain these phenomena that the theory of the tides was fully understood. The weight of a body on the surface of the earth arises from the tendency which the particles composing it have to the centre (or to a point near the centre), in obedience to the law of gravity. But as every object on the earth's surface gravitates towards the sun and moon, as well as towards the earth, it follows that the solar and lunar attraction must affect the weight of terrestrial objects. Upon solid bodies, between the particles of which adhesive force is powerful, no discernible effects are produced by this attraction. But the case is altogether different with regard to the waters of the ocean, the component particles of which yield to the slightest impulse; so that any alteration in their weight that does not equally affect the whole must be followed immediately by a motion of the parts of the fluid mass, which will continue until, by a new arrangement of the particles, the equilibrium is restored.

491. To see what must be the general effect, arising from the action of the sun, if the whole surface of the globe were covered with water; let A C B O be the watery sphere, S the sun, and E the centre of the earth. Let the gravitation of the central particle E to the sun be represented by the lines E S, and the

figure is so small, that its effect in changing the spheroidal figure of the waters on the surface of the earth must be quite inconsiderable. If the earth were at rest, the watery spheroid would acquire that form which would produce an equilibrium among all its particles. This, however, can never happen under the actual circumstances of the case, because some time must elapse before an accelerating force can produce a finite change in the disposition of the waters; but, by the motion of the earth on its axis, the disturbing force is every instant applied to a different part of the surface, so that the position of equilibrium can never actually be attained. Such, then, is the general effect which the solar action would produce if the whole globe were fluid, or a spherical nucleus covered with a fluid of equal density. To explain the phenomena of the tides, however, it is indispensably necessary to take into account the action of the moon.

495. *It is with the moon that the tides are principally connected; and the sun's influence is known only by its increasing or diminishing the effects of her more powerful action.* This greater influence of the moon in producing the tides arises from her vicinity to the earth, when compared with the sun, her distance being only about $\frac{1}{400}$ part of his. It must be carefully kept in view, that it is not the mere action of the sun and moon that produces the tides in the ocean, but the *inequalities* in the action of each: and the gravitation of the waters of the ocean to the moon is much more unequal than their gravitation to the sun. Whatever has been proved with regard to the influence of the sun in producing tides in the ocean is equally applicable to the moon. The waters will be accumulated immediately under her, and on the opposite side of the globe, producing a spheroid of the same kind with that which we have shown must be produced by the unequal action of the sun, but more elongated; and this spheroid, directed toward the moon, will follow her in her apparent daily revolution about the earth. In consequence of this simultaneous gravitation towards both luminaries, the ocean must assume a figure different from both of these spheroids; which will become blended and undistinguishable. The resulting figure resembles each of the spheroids in being elongated, and its most elevated parts are found to follow the more powerful of the disturbing bodies, namely, the moon, in her apparent diurnal revolution about the earth. We may, without sensible error, suppose that the change produced in any part of the ocean by the combined action of the sun and moon, is the sum or the difference of the changes which they would have produced if acting separately.

496. *We have already remarked that the rapid motion of the waters, in consequence of the diurnal motion, prevents them from ever assuming the figure which would be requisite for the equilibrium of the forces acting on them; so that they oscillate continually, alternately approaching to that figure and receding from it.* The motion thus communicated to them is one not of transference, but of undulation, one part rising and another sinking, unless when from want of depth of water the balance between the adjacent columns is destroyed. We may, therefore, regard the two elevations produced in the ocean by the inequalities in the solar and lunar actions as two vast waves which follow the moon in her apparent diurnal motion. The line joining the tops of these two waves is not directed to the moon, as would be the case if the earth and moon were at rest, but is directed to a point about 30° to the eastward of the moon. This arises from the *inertia* of the water, which causes it, when once put in motion, to continue to rise for a time after the impulse communicated has ceased. If we consider the tides relatively to the whole surface of the globe, there is a meridian, therefore, about 30° eastward of the moon where it is always HIGH WATER, both in the hemisphere where the moon is, and the opposite hemisphere. On the west side of this meridian the tide is *flowing*, and on the east side of it the tide is *ebbing*. On the meridian which is at right angles to the former, it is every where LOW WATER. If we suppose, then, the sun and moon to be in the equator, and an observer to be situated on the surface of the water under the equator; when the moon has risen 30° above his horizon, the state of the tide to that observer will be low water. As the moon advances towards his zenith, the tide will flow; and when she has reached a point about 30° to the westward of his zenith, the summit of the wave will reach him, and then the state of the tide will be high water. As the moon approaches the western horizon, the observer will see the water gradually subside as it had formerly risen; and when she has descended 30° below the horizon, it is again low water. As the moon continues her course below the horizon, the waters again gradually rise by the approach of the other wave until its summit arrives at the observer, and again produces high water; when the moon has passed the opposite meridian, and reached a point 30° beyond it, the tide again begins to ebb as the wave rolls on, and the same phenomena are repeated in the same order. Thus, in the space of time in which the moon performs her diurnal revolution, which may be called a lunar day, and consists of nearly $24^h 50^m$, there occur two tides of flood and two of ebb. The time between one high water to the next is about $12^h 25^m$, and the instant of low water is nearly but not exactly the middle of this interval, the tide in general taking about nine or ten minutes more in ebbing than in flowing.

497. *Spring and neap tides.* As the magnitude of the two waves which produce the rise and fall of the tide depends on the action of the sun as well as on that of the moon, it is evident that the height to which the water rises and falls must be affected by the relative position of the

two luminaries. At new moon and full moon the actions of the sun and moon are combined, but at the quadratures they counteract each other. In the former case, the two spheroids produced by the solar and lunar actions have their axes coincident or nearly so; in the latter, their axes are at right angles to each other. Hence, at new and full moon the flood tide will rise higher, and the ebb tide will sink lower, than usual. The reverse of this will happen when the moon is in either of her quadratures: the flood tide will not rise so high as usual, nor will the ebb tide sink so low. This is exactly coincident with experience; and we here perceive the cause of what are called *SPRING TIDES* and *NEAP TIDES*. About the time of full moon and change the tides rise higher than when the moon presents any other phasis. The highest tide does not happen, however, the first after the opposition or conjunction, though the disturbing forces are then united, but some time after; and the cause of this is the same which prevents the time of high water of any one tide coinciding with the time of the moon being on that meridian under which the tide happens; namely, the *inertia* of the water, or that tendency which all matter has to retain its state whether of rest or motion. At Brest, where an accurate register was kept of the phenomena of the tides about the beginning of the last century, it was found that the highest tide happened about a day and a half after the new and full moon. If the time of high water coincide with the very time of conjunction or opposition, the third high water after that is the highest of all. This is called the *SPRING TIDE*. From this period the tides gradually decrease, until the third high water after the moon's quadrature, which is the lowest of all, and is called the *NEAP TIDE*. But having reached their utmost depression, the tides again increase until the occurrence of the next spring tide; and so on continually. The higher the tide of flood rises, the lower the ebb tide generally sinks on that day. The total magnitude of the tide is estimated by the difference between high and low water. At Brest the medium spring tide is about 19 feet, and the medium neap tide about 9 feet.

498. *Effect in different hemispheres.* Let us next suppose the sun and moon to be situated in one of the tropics; the two waves raised in the ocean by their actions on opposite sides of the globe will now roll along under the tropics. If an observer be placed on the surface of the water, and under the same tropic in which the sun and moon are situated, he will still see two tides of flood and two of ebb; but they will not correspond in all their circumstances, as they did on the former supposition. The depth of the high water produced by the wave situated in the same hemisphere with the moon, will evidently be greater than that of the high water produced by the wave which rolls along under the other tropic in the opposite hemisphere from the moon; for the observer will see the very summit of the one wave, and only the sloping side of the other. To an observer situated under the tropic on the opposite side of the equator from the sun and moon, the case would be reversed; and if he were so far removed from the equator as to be situated under the polar circle, no part of the wave accumulated in the same hemisphere with the moon would reach him; so that he would see only one tide of flood and one tide of ebb daily produced by the motion of the other wave.

499. *This also is consistent* with what we know respecting the tides from observation. All the phenomena are found to be modified by the latitude of the place of observation; and some phenomena are found to occur in high latitudes, which are not at all seen when the place of observation is under the equator. In particular when the moon and the observer are on the same side of the equator, that tide in which the moon is above the horizon is greater than the other tide of the same day which happens when the moon is below the horizon. The contrary takes place when the moon and the observer are on opposite sides of the equator: in this latter case, if the polar distance of the observer be equal to the moon's declination, he will see but one tide in the day, continuing to flow for twelve hours and to ebb for twelve hours. We have supposed for simplicity the sun and moon to be in the equator, or in one of the tropics; but it is evident that this can seldom be the case. The two luminaries are capable of an infinite variety of positions in reference to each other, as well as in reference to any particular point of the earth's surface. The phenomena with regard to particular places must, therefore, be endlessly diversified; but by tracing the general features, the principles become apparent upon which all the phenomena depend.

500. *The influence of the sun and moon in producing tides* in the ocean will evidently be *augmented when these bodies are nearer to the earth*, and diminished when their distances are increased. From this cause it arises, that when the moon is in that part of her orbit where she approaches nearest to the earth, the spring tide which happens at that time is the highest, and the next spring tide is the smallest; because the moon is then nearly at her greatest distance from the earth. This makes a difference of $2\frac{3}{4}$ feet from the mean height of the spring tide at Brest; and consequently of double that quantity, or $5\frac{1}{2}$ feet, between the greatest spring tide and the least. The neap tide which happens between these two very unequal spring tides is regular, because the moon is then nearly at her mean distance. The reverse of this takes place when the moon is at her mean distance at the time of the change: the spring tide is regular, but the two neap tides differ considerably in height. The increased distance of the sun is the reason why the spring tides in our summer are not so great as in our winter. At the mean intensities of the disturbing forces, the sun tends to raise the waters about $24\frac{1}{2}$

inches, and the moon about 58. Hence the spring tide should be about $58 \times 24\frac{1}{2} = 82\frac{1}{2}$ inches, and the neap tide about $58 - 24\frac{1}{2} = 33\frac{1}{2}$ inches.

501. *Variations caused by continents, islands, &c.* We have hitherto supposed the two waves which produce the phenomena of the tides to meet with no interruption in their progress round the world. This is, however, far from being the case; they are interrupted by continents and islands, and may be propelled or retarded by the action of the wind; their velocity and direction may also be changed by irregularities in the bed of the ocean: so that, to explain all the phenomena at any particular place, the effect of local circumstances, which is often great, must be taken into the account. The great Pacific Ocean is, perhaps, the only part of the terraqueous globe in which all the forces have room to operate. But the wave which they form must, in rolling westward, encounter the coasts of Asia and New Holland, with the interjacent islands; and amidst these obstacles it must force its way to the Indian Ocean. Its figure will thus be changed, and the phenomena of the tides, which it produces, powerfully modified. On its eastern side the Pacific is bounded by a vast stretch of coast, extending without interruption from Cape Horn to Behring's Straits. This barrier prevents all supply from the eastward for making up the watery spheroid, and must be equally effectual in arresting the progress of the waters accumulated to the eastward of the American continent. So far as we have information respecting the tides in the Pacific Ocean, they appear to be very unlike the European tides, until we reach about 40° or 50° west from the coast of America. In the neighbourhood of that coast, scarcely any tide occurs when the moon is below the horizon. Even in the middle of the Pacific Ocean the tides are very small, but at the same time very regular.

502. As a great extent of surface is necessary in order that the sea should be sensibly affected by the inequalities in the actions of the sun and moon, the *tides* which are experienced in narrow seas, and on shores far removed from the main body of the ocean, are not produced in those seas, but are waves propagated from the great diurnal undulation, and moving with much less velocity. The tides which visit our own coasts must, in a great measure, be supplied from the accumulation of water in the Indian and Ethiopic Ocean, from the eastward, and by what is brought or kept back from the South Sea. The undulations will be diffused as proceeding from a collection coming round the Cape of Good Hope, and round Cape Horn. Consistently with this supposition, it is found that high water, which occurs at the Cape of Good Hope at new and full moon about three o'clock, is later and later as we proceed northward along the coast of Africa; later and later still as we follow it along the western coasts of Spain and France, until we reach the mouth of the English Channel. The wave now divides itself into three branches; one part passing up St. George's Channel, another proceeding northward along the western coast of Ireland, and the third passing up the English Channel, between the British and French coasts. The two branches that proceed along the east and west sides of Ireland unite and form one ridge or wave, which continues its progress along the western coasts and islands of Scotland, and then diffuses itself eastward towards Norway and Denmark, and circling round the eastern coasts of Britain, comes southward through the German Ocean, until it reaches Dover, where it meets the branch which passes up the English Channel. It is to be remarked, however, that this tide which comes up the channel is not the same with that which meets it from the north, but is a whole tide earlier if not two, as appears from the fact of the spring tide at Rye being a tide earlier than the spring tide at the Nore: it even seems two tides earlier, for it appears the one as often as the other. By tracing the hour of high water from the Lizard up St. George's Channel, and along the west coasts of Scotland, it appears that the two tides which pass along the east and west sides of Ireland, and unite into one wave to the north of it, travel round Britain in about twenty-eight hours, in which time the primitive tide has gone round the whole circumference of the earth, and nearly 45 degrees more. By attending also to the successive hours of high water along the western coasts of Africa and Europe, it appears that the wave, which divides into three branches at the mouth of the English Channel, takes up nearly two days, or between four and five tides, in travelling thither from the Cape of Good Hope. A similar progress of the same high water from the southward is observed along the eastern shores of South America; but beyond Brazil and Surinam the Atlantic Ocean is sufficiently extensive to contribute greatly to the formation of the regular spheroid; so that the effect of this high water from the southward, being blended with the tide raised in the Atlantic itself, becomes insensible. In an ocean of such a breadth from east to west as the Atlantic, the water can rise on the one shore only by descending on the other. In the middle, therefore, it will retain nearly the mean height between its elevations on the two opposite coasts: this appears to be the reason why the tides are small in islands that are very far distant from the shores.

503. *The reflection of the tide from shore to shore* is a great cause of irregularity in the tides. The coasts may be so situated that the time in which the undulation that constitutes the tide would of itself vibrate backward and forward from shore to shore, may be so exactly accommodated to the recurring action of the moon that the succeeding impulses, being always added to the natural undulation, may raise it to a height altogether disproportioned

to what the action of the moon can produce in the open sea, where the undulation diffuses itself to a vast distance.

504. *The inequalities which undoubtedly obtain in the bottom of the ocean affect the tides*, by changing the direction of the waters; also their velocity either absolutely or in respect of particular places. They may also influence the height by causing the tide to rush with increasing velocity toward a particular point, where the waters must at length be suddenly checked, and therefore be accumulated in an extraordinary degree: this appears to be the cause of the astonishingly high tides which occur in the Bay of Fundy. The high water of the Atlantic Ocean at St. Helena does not exceed four or five feet; but, setting in obliquely on the coast of North America, it seems to range along that coast in a channel or bed, gradually narrowing till it is stopped in the Bay of Fundy, where the accumulation of the waters becomes tremendous. The tide approaches with a prodigious noise in one vast wave, that is seen thirty miles off, and the waters rise from a hundred to a hundred and twenty feet in the harbour of Annapolis Royal; the rapidity of the waters is so great as to overtake animals feeding on the shores.

505. *In consequence of the length of time required for a tide to propagate itself up a great river*, one or two succeeding tides may reach the mouth of the river before the first tide has arrived at the highest point to which it ranges up the stream. The second tide will also have propagated itself so far up the river, by the time that the third tide reaches the mouth; and thus there may be three co-existent high waters in the river. The two intervening low waters in the ocean will also produce two corresponding low waters in the river: these changes in the depth of the stream are produced by the high waters which arrive at its mouth checking its velocity, and the low waters accelerating it. To cause high water at any particular point, it is by no means necessary that the water should be raised to that level all the way from that point to the mouth of the river. Before such an accumulation could take place, in many instances, places farther down the stream would be inundated. At many places that are far from the sea, the stream at the moment of high water is down the river, and sometimes it is considerable. At Quebec, the current in the St. Lawrence runs at the rate of not less than three miles per hour: this is a clear proof that the water is not heaped up, for there can be no stream without a declivity. The phenomenon termed the *BORE* of a river, which occurs chiefly in large rivers that have a wide outlet, and where the greatest tides are experienced, arises from the waters accumulated in the gulf or outlet by one tide not being, in such circumstances, discharged before the approach of the ensuing tide. These accumulated waters encounter, therefore, the waters of the ocean flowing in an opposite direction; so that the re-action of the conflicting waves produces an elevation of the water far above the natural level. The surge formed in this manner rolls up the river with irresistible force, overwhelming every thing which it encounters; until, exhausted by the resistance which it has to overcome, it at length sinks into a feeble undulation. The violence and elevation with which the bore rushes along in some rivers is almost incredible: at the mouth of the Severn the flood comes up in one head about ten feet in height; but in the great rivers of America, and particularly in the Amazon, it becomes a rolling mountain of water, which is said to attain the height of 180 feet.

506. *In confined seas of small extent*, such as the Caspian, the Euxine, the Baltic, and the great lakes of North America, the tides must necessarily be almost insensible; the disturbing forces in such situations have not room to act to any extent: the greatest height to which the waters of the Caspian can rise above their level on the shore, in consequence of a spheroidal shape being given to them by the lunar action, does not exceed seven inches; an accumulation which a slight breeze of wind is sufficient to counteract. Even in cases where a confined sea is connected with the ocean by a narrow channel no sensible tide can happen; for the tide in the ocean cannot diffuse itself through the contracted inlet during the period that elapses between two consecutive tides.

507. *The Mediterranean is a confined sea of considerable extent*; and the tides there might be very sensible if the effects of the solar and lunar actions were not diminished by its distance from the equator. As the moon approaches the meridian of the eastern part of the Mediterranean, there is a considerable elevation of the waters on the Syrian coast, and a considerable depression at Gibraltar. In the middle of the length the water is at the mean height; in the Atlantic Ocean, an open and extensive surface of water, the regular spheroidal form is nearly attained, and the water stands considerably higher on the outside of the straits than on the inside; it is nearly low water within, while it is about one third or one half flood without. Notwithstanding this accumulation, the communication is too narrow to allow the tide of the ocean to diffuse itself in a regular manner into the basin of the Mediterranean. As the moon moves westward, toward Gibraltar, the water will begin to rise, but slowly, within the straits, while without it is flowing very rapidly. The accumulation within increases with the progress of the moon westward, until it reaches high water; but by this time the tide has been ebbing for some hours without the straits. It will now be low water on the coast of Syria; and during all this time the water at the middle between the eastern and western extremities will not have sensibly altered its depth.

508. *The singular currents which prevail in the Straits of Gibraltar* appear in a great measure explained by these peculiarities with regard to the tides in the Mediterranean Sea and Atlantic Ocean. Changes of tide, always different and frequently quite opposite, are observed on the east and west sides of the narrow neck which connects the rock with Spain; and the general tenor of those changes has a very great analogy with what has now been described.

509. *It is a fact which strikes the attention*, upon the most cursory observation of the phenomena of the tides, that they fall later every day. This variation in the interval of the tides is called the PRIMING or LAGGING of the tides, according as we refer them to lunar or solar time. If we suppose the sun and moon to be in the equator, and the watery spheroid to attain *instantaneously* the form suited to its equilibrium, then the line joining the summits of the two waves produced in the ocean by their combined actions will always be directed to a point situated between their centres; except in the case of the sun and moon being in conjunction or opposition, when it will be directed towards their centres. The following table, calculated on the above supposition, and for the mean distances of the sun and moon from the earth, exhibits the minutes of solar time that the moment of high water precedes or follows the moon's southing, corresponding to every tenth degree of the moon's elongation (eastward) from the sun or from the point opposite to the sun. It shows also the hour and minute of the day, nearly, when it is high water; and the height of the tide, supposing the height of a spring tide to be 1000:—

Moon's Elongation at southing.	Time of High Water.		Height of Tide.	Time of High Water.		Moon's Elongation at southing.
	Before Moon's southing.	Afternoon or Midnight.		Afternoon or Midnight.	After Moon's southing.	
Deg.	Min.	Ho. Min.		Ho. Min.	Min.	Deg.
0	0	0 0	1000	12 0	0	180
10	11½	0 28½	987	11 31	11½	170
20	22	0 58	949	11 2	22	160
30	31½	1 28½	887	10 31	31½	150
40	40	2 0	806	10 0	40	140
50	45	2 35	715	9 25	45	130
60	46½	3 13½	610	8 46½	46½	120
70	40½	3 59½	518	8 0½	40½	110
80	25	4 55	453	7 5	25	100
90	0	6 0	429	6 0	0	90

510. *If we note the exact time of the high water of spring tide for any harbour*, and the exact position of the sun and moon at that time, we can easily make a table of the monthly series for that port, by noticing the difference of that time from the table, and making the same difference for every succeeding phasis of the tide.

CHAP. XVIII.

GENERAL VIEW OF THE SOLAR SYSTEM.

511. *Ten stars*, among the countless number with which, in a clear night, the heavens appear so resplendent, have been proved, by the observations and reasonings of which we have now given a brief outline, to be *planets* revolving about the sun, and deriving their light from him. The earth which we inhabit has been proved to have a similar motion, and to belong to the same class of bodies. Several of these primary planets are accompanied by satellites; and the whole are preserved in their respective orbits by a centripetal combined with a centrifugal force. Thus there subsist among these bodies relations which are regarded as uniting them in one system, having the sun in the centre; and which is therefore called the SOLAR SYSTEM.

512. *In regard to the other planets*, as we have employed the obvious analogy subsisting between them and our earth, in proving its annual and diurnal motion; so, on the other hand, from the same grounds, it seems reasonable to conclude that, like the earth, they are designed and fitted by Infinite Wisdom for the accommodation of inhabitants, and that in all probability millions of beings are placed upon them. Though our observations in relation to the subserviency of the arrangements of nature to the enjoyment of sentient beings is confined to this narrow scene; yet, seeing this small portion of the universe crowded with examples of utility, why should we imagine that Divine Goodness has not throughout the system in like manner diffused its bounty? As our knowledge of the celestial phenomena is extended, the probability becomes proportionably stronger that the other planets are stored with inhabitants who share in the blessings of rational and sentient existence. Their rotation, their *atmospheres*, of which the telescope has enabled us to detect the existence, and the changes which we see going on in these atmospheres, so much resemble what we experience on the earth, that no man who clearly conceives them can divest his mind of the thought that this is not the only part of the system where the Creator has displayed his bounty by giving existence to sentient beings. There is nothing that forbids us to suppose that in each of the other planets there is the same inexhaustible store of subordinate contrivances that we see here for living creatures in every situation, possessing appropriate forms, desires, and abilities. Before abandoning such an opinion, there may surely be expected, from those who require us to do so, some good reason for its rejection.

513. *In regard to the fixed stars*, as the sun, if viewed from a sufficient distance, would be diminished into a luminous point, while the planets that revolve round him would become invisible; so, on the other hand, it is highly probable that each fixed star is itself a sun, and the centre of a particular system, being surrounded with a certain number of planets and comets, which at different distances, and in different periods, perform their revolutions around it.

514. There appears strong reason to suppose that *the sun, with his accompanying planets*, has a motion among the fixed stars, round a centre. From a comparison of ancient and modern observations, it appears that while the stars in one quarter of the heavens are receding from each other, those in the opposite region are gradually approaching. Dr. Herschel has found that these motions of the stars are nearly in the direction that would result from a motion of the sun towards the constellation of Hercules. It is the opinion of Lalande that there is a kind of equilibrium among all the systems of the universe, and that they have a periodic circulation about their common centre of gravity.

CHAP. XIX.

FIGURE AND MAGNITUDE OF THE EARTH.

515. *We have sufficiently established the important proposition that the earth is a round body; and have inferred from the figure of its shadow, as seen on the moon's disc in lunar eclipses, that it must be a sphere, or at least that it approaches to that figure. The hypothesis of its being exactly spherical is sufficient to explain, in a satisfactory manner, the general appearance of the heavens, as seen from different points of its surface; and before the true doctrine of motion and the law of gravitation, which connects the most remote bodies in the universe, were discovered, a sphere was considered to be an exact representation of its shape, and the ingenuity of mathematicians was exerted to discover its magnitude.*

516. *The determination of the magnitude of the earth might appear, to one altogether ignorant of mathematical science, as a problem of insuperable difficulty, and, indeed, as too sublime to be resolved by a human being. If, however, we suppose the earth an exact sphere, the theory of the solution is by no means difficult; it is within the bounds of elementary geometry, and has been known from the earliest ages: but the case is very different with the practice. In the actual resolution, instruments of the greatest nicety are required; and to produce these, the ingenuity of man has been tasked to the utmost during the last two hundred years; besides, the application of them demands, in addition to the principles of geometry, some of the most refined theories in physics: so that, on the whole, few problems present a more ample field for the exertion of the mind of man, or have more extensively called forth the assistance of arts and sciences.*

517. *It is now about two thousand years since Eratosthenes attempted to resolve this important problem. He knew that on the day of the summer solstice the sun illuminated the bottom of a well at Syené. At the same instant he observed at Alexandria that the sun was $7^{\circ} 12'$ from the zenith: and it was supposed that Syené was due south from that place, and therefore that both were under the same meridian. Let C (fig. 42.) be the earth's centre, A Alexandria, Z its zenith in the heavens, B Syené, and S the sun at the instant when it illuminated the bottom of the well, and consequently was in the zenith of that place. The angular measure of the celestial arc ZS, or the corresponding terrestrial arc AB, is the angle ZCS at the earth's centre. Eratosthenes observed the angle ZAS, which, by the elements of geometry, is less than the former by the angle ASC. However, this difference is so small, that it may be altogether neglected in the present case; and thus the angle ACB will be nearly $7^{\circ} 12'$, that is, one fiftieth part of 360° ; and consequently the arc AB of the terrestrial meridian one fiftieth of the*

earth's circumference. The distance between Alexandria and Syené had been determined to be 5000 stadia. Hence it immediately followed that the earth's circumference was 250,000 stadia. As it could not be supposed that this result was very accurate, Eratosthenes reckoned the circumference to be 252,000 stadia, which give in round numbers 700 stadia to the length of a degree.

518. *The geometrical principle here employed was quite correct, and indeed was the same which is used at this time; but the data were very inaccurate and uncertain, for Syené, instead of being exactly south from Alexandria, lies considerably to the east; and it may well be supposed that the assigned distance between Alexandria and Syené was not an accurate measurement, but merely a rude approximation. It is impossible, however, now to determine how near Eratosthenes came to the truth, for want of a knowledge of the exact length of the stadium by which the distance was reckoned.*

519. *The principles by which Eratosthenes was directed in his measurement of the earth appear to have been afterwards employed by Posidonius. This astronomer had remarked, that at Rhodes the star Canopus was just visible in the horizon, but never rose above it; while at Alexandria it attained an altitude of $7\frac{1}{2}^{\circ}$, or $\frac{1}{48}$ th part of the circumference of a great circle. The direct distance between these two places, which were supposed to be on the same meridian, was accounted to be 5000 stadia; and therefore, according to this observation, the circumference should have been 240,000: but here the uncertainty of a distance reckoned by a sea-voyage, not to speak of other causes of error, renders the conclusion of no value.*

520. *About the year 800 of the Christian era, the caliph Almaman directed that his astronomers should measure a degree of the meridian in the plains of Mesopotamia. The method which they employed was susceptible of greater accuracy than that of the Greeks.*

They divided themselves into two parties: after observing the altitude of the pole, one went directly north and the other south, measuring as they proceeded, and taking from time to time the altitude of the pole, until each party had changed its latitude by a degree. Thus the measure of two degrees was obtained; but, at the present time, our ignorance of the exact length of the unit of measure renders all their labour useless to us, even if (what is very unlikely) its accuracy might have been relied on. It appears, however, that their estimation of the earth's magnitude was less accurate than that of the astronomer of Alexandria.

521. *The method of Eratosthenes was practised in modern times, first by Fernel, a Flemish physician. He travelled from Paris towards Amiens, which places are nearly under the same meridian, until he had passed over a degree of latitude; and, by a contrivance attached to the wheel of his carriage, he ascertained the number of revolutions it made in that distance. In this way he found the length of the degree to be 57,070 French toises.*

522. *The same degree was afterwards measured by La Caille, and found to be 57,074 toises. The near agreement of Fernel's result with this last, obtained by a more accurate and scientific process, is very remarkable.*

523. *The Dutch astronomer Snellius was the first who attempted to resolve this most interesting and difficult problem in practical geometry with those scientific aids which its importance required. In the year 1617 he published his *Eratosthenes Batavus*, in which he has detailed the whole process. The extreme points of his meridional arc are terminated in the parallels of Alcmaer, in lat. $52^{\circ} 40\frac{1}{2}'$, and Bergen-op-Zoom, lat. $51^{\circ} 29'$, the arc between them being $1^{\circ} 11\frac{1}{2}'$. He formed a series of triangles between these places along the earth's surface, and determined (as well as the imperfect instruments of the time enabled him to determine) their angles; and by several base lines, actually measured, he found their sides. He reduced the positions of his stations to the meridian; and he concluded that a degree of the meridian was 28,500 perches, which were equivalent to 55,100 toises of that period; which, however, were rather longer than the toise as it is now estimated. The error of Snellius appears to have been about 2000 toises on the length of a degree, of which 1900 may have arisen from the error in measuring the celestial arc, and the rest from the imperfection of his geodetical measurements. Snellius measured his original base over again, and corrected his conclusion: he died, however, before he could publish the result. Cassini made certain corrections in his calculations, by which the length of the degree came out 56,675 toises; and Muschenbroek, by an examination of Snellius's papers, found that the degree ought to have been reckoned 57,033 toises.*

524. *Our countryman Richard Norwood made a remarkable approximation to the true length of a degree in 1635, by apparently inadequate means. He measured the distance between London and York, observing the bearings as he proceeded, and reducing all to the direction of the meridian and the horizontal plane. He determined the difference of latitude to be $2^{\circ} 28'$; and from the whole distance he determined the degree to be 367,176 feet English, or 57,800 toises.*

525. *As far as pure mathematical theory was concerned, the method of Snellius was excellent; the chief imperfection was in his instruments: but an immense improvement was made by Picard, in the application of the telescope and the micrometer to the measurement of angles; and, with the assistance of instruments constructed on the new principle, this astronomer, by the direction of the French Academy, began the measurement of an arc of the meridian, taking for its extremities the parallels of Sourdon near Amiens, and Malvoisine. His general manner of conducting the process was the same as that of Snellius. He connected the extreme parallels by a series of triangles, the sides of which were determined from a base of 5663 toises, measured twice with great care at one extremity of the series. There was a base of verification of 3902 toises measured at the other extremity. The horizontal angles were measured by a quadrant of thirty-eight inches' radius; and the celestial arc, which was about $1^{\circ} 12'$, by a sector ten feet in radius. He concluded the length of a degree to be 57,060 toises.*

526. *This was the first measurement in which confidence could be placed. It is true there were several elements wanting in the determination of the celestial arc, owing to the imperfect state of astronomical science at that time; but, by a fortunate compensation, the errors thence arising corrected each other. This measurement of Picard was of service to Newton, in verifying his happy thought of the law of universal gravitation.*

527. *The measurement begun by Picard was continued northward to Dunkirk by La Hire; and in the opposite direction, as far as Perpignan, by the second Cassini, who published the whole in 1718, in a work on the magnitude and figure of the earth.*

528. *The labour of the French astronomers determined the magnitude of the earth with a degree of accuracy sufficient for the general purposes of geography; but science was now proceeding with rapid strides, and a new question was agitated, — Is the earth an exact sphere, as had been hitherto supposed? or, if it be not a sphere, what is its true figure?*

529. *Huygens and Newton had established the doctrine of the centrifugal force of bodies*

revolving in circles; and from this it was justly inferred that the earth, in consequence of its rotation on an axis, must necessarily deviate from a spherical figure, and assume that of an oblate spheroid; that is, a solid generated by the revolution of an ellipse on its lesser axis, the extremities of which in this case were the poles.

530. *This opinion received support from some astronomical observations made by Richer, who was sent by the Academy of Sciences, in 1672, to Cayenne. He there found that his clock, which had been regulated to mean time at Paris, went slower by a sensible quantity. This interesting observation showed that the weight of the pendulum was less at the equator than it had been at Paris; and hence the diminution of the force of gravity in proceeding from the equator towards the pole, as shown theoretically by Newton, was completely established; and consequently also the oblateness of the earth at the poles, and its elevation at the equator, which are the consequence of this diminution.*

531. *If the earth were a perfect sphere, then all the degrees of the terrestrial meridian from the equator to the pole would be equal in length. But this will by no means be the case if the earth be a spheroid. For, supposing the earth to be an oblate spheroid (fig. 43.), of which the lesser axis is PP' , that diameter of the earth which passes through PP' the poles. Let EQ be any equatorial diameter, and $EPQP'$ a section of the earth, through the axis PP' , which will therefore be a terrestrial meridian. Because the direction of gravity is always in a line perpendicular to the earth's surface; at the poles and equator, the direction of gravity will pass through the centre. It will be otherwise, however, at any point, D , between the equator and*

poles; for, by the nature of the ellipse, a line, DF , drawn perpendicular to the curve at D will pass on one side of the centre. Now let us suppose that DF , HF , are two straight lines perpendicular to the earth's surface at D and H , which meet in F , and contain an angle, DFH , of one degree; also let GK , LK , be other two lines perpendicular to the earth's surface at points nearer the pole; and suppose these also to contain an angle, GKL , of one degree. The elliptic arc DH , because of its smallness, may be considered as an arc of a circle of which DF or HF is the radius; and similarly, the elliptic arc GL may be considered as an arc of a circle whose radius is GK or LK . The curvature of the ellipse is greatest at E , the extremity of the greater axis, and gradually decreases to P , the extremity of the lesser axis, where it is least. Hence the arc DH will be more incurvated than GL ; and since the angle at F and K are equal, each being one degree, the almost equal lines GK , LK , will be greater than the almost equal lines DH , HF ; and the arc GL must therefore be greater than the arc DH . Thus, if the earth is an oblate spheroid, a degree of the terrestrial meridian will, by actual measurement, be found to be least at the equator; and the degrees will gradually increase as we proceed towards either pole.

532. *It is manifest that the case would be just the reverse if the earth were an oblong spheroid, generated by the rotation of an ellipse on its greater axis EQ . Hence the important question, What is the figure of the terrestrial meridian? may be resolved by measuring arcs of the meridian in different latitudes.*

533. *None of the measurements before that begun by Picard were made with such accuracy as to enable mathematicians to resolve the question. But it was then supposed that this had been performed with such care as to afford the necessary data. Such, however, appears not to have been the case. The degrees actually measured were found to be unequal; but, instead of increasing in going from south to north, the reverse was supposed to be the fact; and had this been really true, the polar axis would have been greater than the equatorial, — a conclusion quite in opposition to the conclusion drawn from the doctrine of centrifugal force.*

534. *To determine this most important question, the Academy of Sciences resolved that degrees of the meridian should be measured in various latitudes which might differ as much as possible; and it was determined that one party should be sent to the neighbourhood of the equator, and another to the polar circle. Two scientific expeditions were accordingly undertaken. Maupertuis, Clairaut, Comus, Lemonnier, and Outhier went to Lapland, where the Swedish astronomer Celsius joined them; and there they measured an arc of fifty-seven minutes of a degree, from which they concluded that a degree under the polar circle, viz. in lat. $66^{\circ} 20'$, was 57,419 toises, that is, about 349 toises greater than that of Paris. This degree has been since remeasured with great care by Swanberg and other Swedish mathematicians, who found it to be 57,196 toises. This is 223 toises less than the determination of the French academicians; but it is certainly more correct.*

535. *The other party, composed of Godin, Bouguer, and La Condamine, performed a similar*

but more extensive operation in Peru. After ten years' labour, they, with the assistance of two Spanish officers, Don Jorge Juan and Antonio de Ulloa, accomplished the measurement of an arc of about $3^{\circ} 7'$. From this they concluded that the length of a degree was 56,758 toises, which was shorter than the French degree by 302 toises. These measurements set the question completely at rest. There could no longer be any doubt that the polar diameter of the earth was shorter than the equatorial.

536. *The measurement of different degrees* has been since performed many times in different countries; as again in France, and also at the Cape of Good Hope, by La Caille; in Italy, by Maire, Boscovich, and Beccaria; in Pennsylvania, by Mason and Dixon; in Hungary, by Liesganig; in India, by Lambton.

537. *There have been, in addition to these*, two admeasurements of arcs of the meridian which deserve particular notice, on account of their extent, the excellence of the instruments employed, and the skill with which the operations have been conducted. We are indebted to the spirit of reform and improvement which sprung out of the French revolution for one of these, and to the liberal and enlightened views of the English government for the other.

538. *The great diversity in the units of a measure* is an evil which has been long felt and complained of in every commercial country. The French Constitutional Assembly took up this most important subject in the year 1790; and, at the suggestion of Talleyrand, it was decreed, that the king should request his Britannic majesty to engage the parliament of England to concur with the National Assembly in fixing a natural unit of weights and measures; that, under the auspices of the two nations, commissioners of the Academy of Sciences, and an equal number of members of the Royal Society of London, should determine the length of the pendulum in the latitude of 45° , or other preferable latitude, and from this deduce an invariable standard for all weights and measures.

539. *The Academy named a commission*, composed of Borda, Lagrange, Laplace, Monge, and Condorcet, who gave a report, which is printed in the Memoirs of the Academy for 1788. Three different fundamental units were suggested in their report. The first is the pendulum which beats seconds in a given parallel. That of 45° was thought preferable to any other, because there the pendulum is a mean among all those which beat seconds in the different latitudes between the equator and the pole. They observed, however, that the pendulum contains a heterogeneous element, namely, time; and an arbitrary element, viz. the division of the day in 86,400 seconds. They, therefore, considered it to be less proper as a standard unit of lineal measure, than another which they regarded as unexceptionable. This is the length of a quadrant of the meridian, a linear magnitude of the same kind as the thing to be determined, and therefore more natural than the pendulum, which involved the consideration of time. There is yet another linear unit, namely, the circumference of the earth's equator. But this is not better known than the elliptic meridian; nor does it admit of being determined with so much precision. On the whole, therefore, it was recommended that the quadrant of the meridian should be taken as the primary unit, and that its ten millionth part (a lineal space about $39\frac{1}{4}$ English inches) should be the ordinary unit for the measurements which occur in the affairs of life. This was named a *mètre*.

540. *Although in the beginning it had been proposed to invite the English philosophers to assist in establishing a standard unit*, yet, as the object to be attained could be accomplished perfectly by the French mathematicians, without any foreign aid, it was recommended to commence immediately the measurement of the arc of the meridian between Dunkirk and Barcelona, an extent of nearly $9\frac{1}{2}$ degrees. The operations necessary for this labour were, 1. To determine the difference of latitude between Dunkirk and Barcelona; and, in general, to make such astronomical observations on the whole line as might be thought useful. 2. To measure again the bases which had served for the measurement of the degree made at Paris, and the construction of the map of France. 3. To verify by new observations the series of triangles which had formerly been employed for the measurement of the meridian, and to prolong them to Barcelona. 4. To make, at the 45^{th} degree, such observations as might determine the number of vibrations which a pendulum equal in length to one ten-millionth part of the meridian would make in a day, in a *vacuum* at the level of the sea, and at the temperature of melting ice, in order that, this number being once known, the *mètre* might be determined at any time by the length of the pendulum. In this way the advantages of the two methods of forming a standard would be united. 5. To verify by new experiments the specific gravity of pure water in a *vacuum*, and at the temperature of water just beginning to freeze. 6. and lastly, To reduce all the old measures of every kind employed in commerce to the new standards.

541. *To accomplish these objects*, it was recommended that six distinct commissions should be appointed. This was done by a decree of the National Assembly, dated 26th March, 1791; only it was thought to be better to commit the astronomical and geodetical observations to a single commission. Immediately directions were given for the construction of the necessary instruments. Lenoir, a celebrated French artist, was employed to make

repeating circles, long rules of platina for the measurement of the bases, and a shorter rule ; also, balls of platina and gold for the pendulum observations.

542. *About the middle of the year 1792, Cassini and Borda began a series of experiments on the pendulum ; and, in the following year, Lavoisier was engaged in experiments on the expansion of metals. And about the same time Mechain began his operations for the determination of the portion of the meridian between Rodez and Barcelona, an extent of 170,000 toises. Delambre had undertaken the portion of the arc between Dunkirk and Rodez, 38,000 toises in extent. This, however, had been twice measured before ; and for this reason the labour was expected to be less than was required for the other portion, which was entirely new. Besides the privations and hardships, the ordinary accompaniments of a service which requires those who perform it to live in elevated situations, with little shelter, with few of the comforts to which they have been accustomed, and exposed to the vicissitudes of heat and cold, and the influence of the nocturnal dews, they had to encounter the perils arising from a disorganised state of society. Mechain was stopped in the neighbourhood of Paris ; but when he pursued his labours at a distance from the capital, he met with no farther interruption ; while Delambre, in the north of France, was often exposed to the most imminent danger. In the heat of the French revolution, the people were jealous of what they did not understand ; and the astronomers were at once exposed to the machinations of their enemies at Paris, and to the brutality of the ignorant peasants in the provinces.*

543. *In the course of their operations they measured two bases, on the accurate determination of which the utility of all their labours was to depend. One base, of 6075·9 toises, was measured by Delambre at Melun ; and the other, of 6006·2478 toises, at Perpignan. The distance between them was 360,330 toises, about 436 English miles. They were connected by a chain of triangles, the sides and angles of which were all known ; so that the length of one base being known, that of the other might be found by computation. It is a remarkable fact, that when the base of Perpignan was inferred by calculation from that of Melun, the result was found to be only about ten or eleven inches less than that obtained by actual measurement. This striking agreement affords a strong presumptive proof of the accuracy with which the operations had been conducted.*

544. *The determination of the latitudes of the two extremities of the arc was also a matter of the utmost importance. The pains which the astronomers took to arrive at true results are almost incredible. Delambre made 800 observations to ascertain the true latitude of the Dunkirk extremity ; and a corresponding degree of attention was bestowed on different intermediate points.*

545. *This most important undertaking was at last, after seven years' labour, brought to a conclusion in the year 1799. Although the result was, in its first application, to be directed to the establishment of a standard unit of lineal measure for the French nation, yet the advantages which may be deduced from it extended much farther, and were available to every nation enlightened by science. For this reason, the states living in peace with France had been invited to send eminent mathematicians and astronomers to assist in a rigorous examination of every step of the operation. The astronomical and geodetical observations, in particular, were subjected to the examination of Tralles, the deputy of the Helvetian republic ; Van Swinden, the Batavian deputy ; and the two French philosophers Laplace and Legendre. They entered into all the details of the measurement of the bases ; and they examined the three angles of every triangle, and determined their values. The calculations were then separately performed by four different persons — Tralles, Van Swinden, Legendre, and Delambre ; and this last astronomer calculated the length of the meridian by four different and independent methods ; and a report was made to the National Institute at Paris, in June 1799, in the name of the Class of Physical and Mathematical Sciences, on the Measure of the Meridian of France, and its Results.*

546. *The general fact, that the degrees of the meridian increase as we recede from the equator towards the pole, was again fully confirmed ; so that the oblateness of the earth in the direction of the polar axis is a truth now placed beyond all controversy. Notwithstanding, however, the almost incredible care with which the operations were conducted, the exact quantity of this compression was still left in some uncertainty. The limits between which the true measure of the oblateness is contained are, however, narrower ; and it is likely that the problem, What is the exact proportion of the polar to the equatorial axis ? does not, from its nature, admit of a nearer approximation to the truth than has been already obtained.*

547. *If we could suppose the measurements of lines and angles to be perfectly correct, it would follow, that although on the whole, taking considerable intervals, the length of arcs of the meridian corresponding to equal celestial arcs go on increasing from south to north, yet the law of the increase is irregular, and not that which ought to result from an exact elliptic meridian. The result of the measurement will be seen in the following table : —*

	Latitudes.	Intervals.	Intervals in Toises.	Length of a Degree.	Mean Latitude.	Arc of one Second.
	° ' "	° ' "		Toises.	° ' "	Toises.
Dunkirk	51 2 9.20	2 11 19.83	124944.8	57082.63	49 56 29.30	15.856283
Pantheon	48 50 49.37	2 40 6.83	152293.1	57069.31	47 30 45.91	15.852586
Evaux	46 10 42.54	2 57 48.24	168846.7	56977.80	44 41 48.37	15.827167
Carcassonne	43 12 54.30	1 51 9.34	105499.0	56946.68	42 17 19.60	15.818508
Montjoux	41 21 44.96					

From this table we see that the length of a degree in the four mean latitudes goes on increasing. Also, from the column of mean latitudes, and that of the length of a degree, it appears that a diminution of $2^{\circ} 25' 43''.39$ in the first mean latitude corresponds to a diminution of 13.13 toises in the terrestrial meridian: this gives 5.5 toises to a degree. Again, that a farther diminution of $2^{\circ} 48' 57''.54$ produces a diminution of 91.51 toises, which is at the rate of 32.4 toises to a degree. Lastly, that a third diminution of $2^{\circ} 24' 28''.77$ gives a diminution of 31.17 toises, which is at the rate of about 12.9 toises to a degree. These changes of 5.5, 32.4, and 31.17 toises in the length of a degree in going southward evidently do not follow a regular law, such as should result from a continuous increase of curvature. We may, therefore, reasonably suppose that all the observations have not been equally perfect, or that, in addition to unavoidable errors in the estimation of lines and angles, some disturbing cause must have operated: probably, an inequality of density, in the density of the strata over which the measurement was performed, may have had great influence in producing the irregularity.

548. *The small discrepancies in the results of the observations* must produce corresponding uncertainty in the determination of the great objects to be attained. On the whole, however, it was concluded that the length of the terrestrial meridian between the pole and the equator was 5,130,740 toises; and hence the mètre, or ten millionth part of the meridian, was .513074 of a toise, which is 443.295986 lines.

549. *Another most important result, deducible from these observations*, was the ratio of the polar axis of the earth to the equatorial axis. This must partake of the uncertainty of the data by which it is to be determined. We may, however, assume, without sensible error, that the equatorial axis is to the polar as 334 to 333. The difference, therefore, of the semi-axes, compared with the equatorial radius, will be one part in 334. The fraction $\frac{1}{334}$, — that is, the difference of the semi-axes divided by the equatorial radius, — is called the *compression* of the earth at the poles.

550. *The astronomer Mechain had contemplated the extension of the measurement of the meridian* beyond the limit at first proposed; but he did not live to carry his views into execution. However, the undertaking was resumed, after a cessation of three years, by Biot and Arago, French astronomers, with whom were associated MM. Chaix and Rodriguez, Spaniards, all eminently distinguished for their talent and devotedness to the object to be accomplished. By their exertions, a train of triangles was carried southward from the point where Mechain and Delambre had stopped, to Formentera, a small island near Ivica, in the Mediterranean. This is the southern limit of a most interesting labour: but, if ever European civilisation extends into Africa, the measurement may be extended to Cape de Gata, and thence across the Mediterranean to the coast of Africa, and continued to the city of Algiers, which is nearly in the meridian of Paris; so that in time the southern extremity may be actually carried to the summit of Mount Atlas.

551. *The other measurement of a considerable portion of the earth*, to which we have alluded, was begun under the auspices and at the expense of the British government as long ago as the year 1784. At that time a memoir, drawn up by Cassini de Thury, was presented to our minister (Mr. Fox) by the French ambassador. It stated the advantages which would accrue to geography and astronomy by determining the difference of longitude between the observatories of Greenwich and Paris, by means of a series of triangles from the former to Dunkirk, to which place the meridian of Paris had previously been extended. The proposal was communicated to the Royal Society; and, having been approved of, the execution was committed to general Roy. The first step was to measure a base, from the length of which the sides of all the triangles might be inferred; and a line rather more than five miles in length was traced out on Hounslow Heath, and measured with the most scrupulous care. It may at first sight appear a very simple matter to measure a straight line on the ground; but if the utmost exactness is required, the operation must be performed with instruments constructed with the greatest ingenuity, and the application of much physical

knowledge. Generally all solid bodies expand by heat, and contract by cold; and, moreover, some change their dimensions by moisture and dryness. To counteract or to estimate precisely these changes, so as to allow for them in the final result, is a matter of great difficulty, and only to be accomplished by infinite care and perseverance.

552. *The measurement of the base was first undertaken with deal rods, twenty feet in length. These, however, were found to be much affected by the changes in the atmosphere from moisture to dryness: they were therefore laid aside; and instead of them glass rods, of the same length in frames, were employed. This substance was chosen, from a belief that it was less affected by changes of temperature than the metals. The measurement, which had been begun about the middle of June, was completed in the end of October; and it was found that the base measured exactly 27404.08 feet, or 5.19 miles.*

553. *The work in the field was not carried farther at that time: it was, however, resumed in 1787. A theodolite of greater dimensions than had ever been employed in geodetical operations was constructed by the celebrated artist Ramsden. The series of observations was begun at the base in the beginning of August, by General Roy, assisted by Isaac Dalby, an excellent mathematician, and most veracious astronomical observer. After continuing to a certain length, it was judged to be expedient to break off, and proceed with the instruments to Dover. A series of observations was there made, in conjunction with the French academicians Cassini, Mechain, and Legendre, by which the triangulation between Paris and Dunkirk might be connected with that between Dover and Greenwich. As a check on the operations, a base of verification was also measured on Romney Marsh; and in this, instead of the glass rods, a steel chain, constructed for the purpose by Ramsden, was employed; it having been found by experience that there was no sensible difference in point of accuracy between this and the glass rods, while the chain manifestly was more convenient. Afterwards, when the two bases were connected by calculating the sides of the triangles, it was found that the measured base differed from its computed value by only twenty-eight inches, although Romney Marsh is more than sixty miles from Hounslow Heath. The junction of the observatories of Greenwich and Paris, by a series of triangles, was completed in 1788, and an account of the operations communicated to the Royal Society; but the death of General Roy again suspended the survey until the year 1791.*

554. *At this time, by the exertions of the Duke of Richmond, Master-general of the Ordnance, the survey was resumed with great vigour. A new theodolite, and various other instruments, in addition to those formerly employed, were liberally supplied, and placed under the direction of Captain (afterwards Colonel) Mudge of the Royal Artillery, and Mr. Dalby. Beginning their labours by a re-measurement of the base on Hounslow Heath with steel chains, they found the difference between this and the former, in which glass rods were employed, to be no more than two inches and three quarters. They also measured another base of verification, 36574.4 feet in length, on Salisbury Plain. When this was connected by a chain of triangles with the base on Hounslow Heath, and its length computed, the result did not differ more than an inch from the actual measurement; a convincing proof of the accuracy with which all the operations had been conducted.*

555. *Although an accurate survey of the island was the main object for which all this labour was undertaken, yet, as its complete accomplishment requires a knowledge of the figure and dimensions of the earth, no opportunity of solving this grand problem is to be neglected. The two stations of Beachy Head in Sussex, and Dunnose in the Isle of Wight, are visible from each other, and more than sixty-four miles asunder, nearly in a direction from east to west: their exact distance was found by the geodetical operations to be 339397 feet. The azimuth, or bearing of the line between them with respect to the meridian, also the latitude of Beachy Head, were determined by astronomical observations. From these data the length of a degree perpendicular to the meridian was computed; and this, compared with the length of a meridional degree in the same latitude, gave the proportion of the polar to the equatorial axis.*

556. *The result thus obtained, however, differed considerably from that obtained by meridional degrees. It has been found impossible to explain the want of agreement in a satisfactory way; and, for this reason, it has been thought better to rest the solution of the problem entirely on the measurement of degrees of the meridian in different latitudes, which, on the whole, give results more consistent with one another.*

557. *Without noticing in detail all the steps by which the survey has advanced, we shall next advert to the measurement of an arc of the meridian between Dunnose, in the Isle of Wight, and Clifton, near Doncaster; the*

former in lat. $50^{\circ} 37' 5''$, and the latter in $53^{\circ} 27' 30''$. To accomplish this, the ingenuity of the artist Ramsden was again exercised in the construction of an instrument, a zenith sector, for finding the latitude of the different points of the arc: this was almost the last work of a man to whose genius astronomy and geography are highly indebted; and it was superior to any thing of the kind ever before constructed.

558. To give the reader a distinct notion of this most important operation, we here present a sketch (*fig. 44.*) of the series of triangles, twenty-two in number, which connect the extreme points, together with the angles contained by the straight lines which join the different stations, and the length of their sides. The numbers marked on the diagram indicate the names of the *stations*, by referring to the following table. The northern extremity of the base, Beacon Hill, or Clifton, is marked No. 3.; and the southern extremity, Dunnose, is 23. The names of the intermediate points may be seen in the table.

No. of Triangles.	Names of Stations.	Angles corrected for Calculation.	Distance.	Feet.
1.	Butser Hill - - (22)	76 12 21.5	From Dunnose to	
	Dean Hill - - (21)	48 4 31.75	Butser Hill - -	140580.4

	Highclere - - (19)	46 10 17.75	Bagshot Heath - -	105321.2
	Nuffield - - (16)	78 17 17	Highclere - -	120374.
6.	White Horse Hill - (17)	63 7 53.5	White Horse Hill from	
	Highclere - - (19)	63 18 17	Nuffield - -	120557.7
	Nuffield - - (16)	53 33 49.5	Highclere - -	108563.1
7.	White Horse Hill - (17)	38 48 12.5	Brill from	
	Nuffield - - (16)	86 4 15	White Horse Hill - -	146603.2
	Brill - - (15)	55 7 32.5	Nuffield - -	92805.5
8.	Brill - - (15)	50 14 45	Stow from	
	White Horse Hill - (17)	64 45 42.5	White Horse Hill	124365.6
	Stow on the Weld - (14)	64 59 32.5	Brill - -	146326.3
9.	Brill - - (15)	32 34 42.25	Epwell from	
	Stow on the Weld - (14)	60 56 5.5	Stow - -	78938.2
	Epwell - - (13)	86 29 12.25	Brill - -	128140
10.	Brill - - (15)	34 23 57.5	Arbury Hill from	
	Epwell - - (13)	85 0 17.5	Epwell - -	83098.4
	Arbury Hill - (12)	60 35 45	Brill - -	146530
11.	Arbury Hill - (12)	89 57 5.5	Corley from	
	Epwell - - (13)	54 45 18.25	Arbury Hill - -	117463
	Corley - - (11)	35 17 36.25	Epwell - -	143827.8

559. The distance of Butser Hill (22.) from Dunnose, 140580.4 feet, had been previously found, by a series of triangles connecting these places with the bases measured on Hounslow Heath and Salisbury Plain; but, for greater security against error, a new base of 26342.7 feet was measured on Misterton Carr, in the northern part of Lincolnshire. From this the sides of the triangles proceeding from the north to the south were computed, as exhibited in the remainder of the table.

No. of Triangles.	Names of Stations.	Angles corrected for Calculation.	Distance.	Feet.
12.	Beacon Hill - (3)	20 47 20	Beacon Hill from	
	North end of Base (1)	60 17 13	North end of Base - -	64461.7
	South end of Base - (2)	98 55 27	South end of Base - -	73321.9
13.	Beacon Hill - (3)	34 44 42	Gringley from	
	North end of Base - (1)	74 46 56	North end of Base - -	44338.2
	Gringley - (4)	70 28 22	Beacon Hill - -	75068.0

	Heathersedge - (5)	39 8 38	Heathersedge - -	101660.3
	Sutton Ashfield - (6)	60 22 25	Sutton Ashfield - -	73826.6
18.	Hollan Hill - (8)	44 43 31	Hollan Hill from	
	Sutton Ashfield - (6)	113 49 7	Sutton Ashfield - -	3.8375.2
	Orpit - (7)	21 27 22	Orpit - -	9.5975.3
19.	Bardon Hill - (10)	42 58 59	Bardon Hill from	
	Hollan Hill - (8)	74 52 37	Hollan Hill - -	124454.7
	Orpit - (7)	62 8 24	Orpit - -	135895.3
20.	Castle Ring - (9)	55 32 43	Castle Ring from	
	Bardon Hill - (10)	68 24 3	Orpit - -	153235.2
	Orpit - (7)	56 3 14	Bardon Hill - -	136717.8
21.	Corley - (11)	72 32 46	Corley from	
	Castle Ring - (9)	47 54 42	Bardon Hill - -	106357.3
	Bardon Hill - (10)	59 32 32	Castle Ring - -	123539.7
22.	Arbury Hill - (12)	34 14 33	Arbury Hill from	
	Corley - (11)	107 20 14	Bardon Hill - -	180426.0
	Bardon Hill - (10)	38 25 13	Corley - -	117457.1

560. From this last triangle the distance between Corley and Arbury Hill comes out 117457.1 feet. This result has been found from the base on Misterton Carr: but the same distance, deduced from the bases on Hounslow Heath and Salisbury Plain, either of which is more than 150 miles distant from Misterton Carr, was found (see triangle 11.) to be 117,463 feet, only six feet different. Here we have a remarkable proof of the extreme accuracy with which the operations have been conducted; so that, from whatever cause any uncertainty in the conclusion sought may proceed, it can hardly be found either in the want of perfection in the instruments, or of care in those who used them.

561. By observations on the pole star, the exact bearing of Butser Hill from Dunnose (that is, the azimuth or angle which the line joining them makes with the meridian,) was found: and by like observations the bearing of the station at Gringley from Clifton was determined. By these data, and by the known lengths of the sides of the triangles, the portions of the meridian intercepted by perpendiculars on it from the stations was obtained. Their sum gave 1,036,337 feet for the meridional distance on the surface of the earth, between Dunnose and Clifton. Moreover, by the zenith sector, the arc of the celestial meridian between them was found to be $2^{\circ} 50' 23'' \cdot 38$, or 2.8398 degrees of difference of latitude. The length of the measured arc of the meridian, viz. 1,036,337 feet, divided by this number, gives 364,933 feet, or 6082 fathoms for the length of a degree in the parallel midway between Dunnose and Clifton, which is $52^{\circ} 2' 20''$.

562. In the same way that the length of a degree, at the middle point between Clifton and Dunnose, was determined, the length of degrees at other intermediate points was found.

The latitude of the station at Arbury Hill was carefully observed with the sector. The latitude of Greenwich was well known; and that of Blenheim, an observatory belonging to the Duke of Marlborough, had been determined from five years' observations. The two observatories were assumed as stations, in addition to those in the meridional chain of triangles, and their position in respect of the others was found.

563. *By comparing the celestial with the terrestrial arcs*, the length of degrees in various parallels was determined, as in the following table: —

				Latitude of Middle Point.	Fathoms.
Arbury Hill and Clifton	-	-	-	52° 50' 29".8	60,766
Blenheim and Clifton	-	-	-	52 38 56.1	60,769
Greenwich and Clifton	-	-	-	52 28 5.7	60,794
Dunnose and Clifton	-	-	-	52 2 19.8	60,820
Arbury Hill and Greenwich	-	-	-	51 51 4.1	60,849
Dunnose and Arbury Hill	-	-	-	51 35 18.2	60,864
Blenheim and Dunnose	-	-	-	51 13 18.2	60,890
Dunnose and Greenwich	-	-	-	51 2 54.2	60,884

This table presents a singular deviation from the common rule; for, instead of the degrees increasing as we proceed from north to south, they appear to decrease, as if the earth were an oblong instead of an oblate spheroid. The oblateness of the earth at the poles is, however, a fact so well established by more extensive measurements, that we must suppose either that some error has been committed in the observations, — a thing, however, not probable; or else, what is more probable, that by inequality in the density of the strata, producing a local attraction, the plumb-line of the sector has suffered a deflection at some of the stations.

564. *Notwithstanding the discrepancy of the results of the measurements in this particular arc*, the length of a degree at the middle station (viz. lat. 52° 2' 20") agrees very well with the measurements of the meridian in France and other places. Indeed, the measurements of the small arcs of the meridian in other countries have presented similar anomalies, although in general not so remarkable. It is, therefore, only by comparison of the measures of extensive arcs at considerable intervals that we can arrive at certain conclusions. The British survey has now been extended from the southern parts of the island to Unst, the northernmost of the Shetland Islands. At present the engineer officers who carried it on are employed in the survey of Ireland; but we may expect that at no remote period they will resume the British survey, and supply the observations still wanting. When this is done, and the complete triangulation is published, it will then appear how far local attraction may have disturbed the plummet in passing over the variety of rocks throughout the island.

565. *Although the compression of the earth be small*, yet an exact knowledge of its quantity is of great importance, because of the deductions which are to be made from it. It has been explained, that the direction of a plumb-line is always perpendicular to the earth's surface; therefore, and because of the continual change of curvature of the meridian in going from north to south, the direction of gravity can only pass through the earth's centre at the poles and equator. Thus it appears that there is a necessary connection between the form of the earth and terrestrial gravity; so that the small variations in the latter, which are owing to the deviations from the exact spherical figure, being known, that deviation itself may be determined.

566. *If the earth were spherical and homogeneous*, the attraction of its mass upon different points of its surface, or the force which solicits every particle of matter at its surface towards the centre, would be every where the same. But the elliptic form produces a small deviation from this equality, which increases in going from the equator towards the poles, as the square of the sine of the latitude; and this would be true even if the earth were at rest: but, by its revolution about its shorter axis, there is produced a centrifugal force, which acts in a direction perpendicular to that axis, and therefore diminishes the force of gravity most of all at the equator, because there the two forces act in contrary directions. At the pole its direction is perpendicular to the direction of gravity, and produces no effect.

567. *By the united operation of these two causes*, in going from the equator towards the poles, is produced a variation in the degree of quickness of descent of a heavy body, which increases as the square of the sine of the latitude.

568. *The oscillations of a pendulum afford a simple means of verifying this fact*. The increase of weight in a heavy body, — that is, the force of gravity in proceeding from the equator

to the poles, — will be indicated by a diminution of the time in which an invariable pendulum performs a vibration. Accordingly the pendulum has been employed to determine the figure of the earth; and the results obtained have been found to accord perfectly with the geodetical measurements which we have described.

569. *The British and French governments have both instituted observations on the pendulum.* The latter, on the recommendation of the Academy of Sciences, directed that the intensity of the force of gravity should be determined at different points of the arc of the meridian between Dunkirk and Formentera; and committed the labour to MM. Biot, Arago, Mathieu, Bouvard, and Chaix: subsequently, Biot extended his observations to the northern extremity of the British islands. These operations were begun in the year 1807. At a somewhat later period the British government, with the assistance of the Royal Society, employed Captain Kater, an eminent observer and experimenter, in the same labour; and also sent Captain Sabine, a British artillery officer, with invariable pendulums to the equator on the one hand, and the highest accessible latitudes of the northern hemisphere on the other. It was expected that, by thus multiplying the places of observation, the combination of results would destroy the irregular influences of local density, and give the true variations of the force of gravity, which are owing to the earth's ellipticity. From a mean of all the observations made by the British and French experimenters, it was found that the compression or ellipticity of the earth was about $\frac{1}{288.7}$ or $\frac{1}{288.86}$. Laplace had previously concluded, from the combined measurements of terrestrial degrees and pendulum experiments, and the lunar inequalities dependent on the figure of the earth, that the same important element was $\frac{1}{288.75}$. There is a difference between the two conclusions; but, on the whole, all the results which have been obtained are comprehended within limits which may be deemed moderate, considering the difficulty of the enquiry.

570. *The following tables exhibit numerical values of the magnitudes of the degrees of latitude and longitude, and their proportion to each other.*

The first is from a valuable collection of astronomical tables and formulæ by F. BAILY, Esq., President of the Astronomical Society of London. It shows the length of a degree of latitude and longitude on the earth's surface, assuming the compression to be $\frac{1}{300}$, together with the length of the pendulum beating seconds there, supposing the compression to be $\frac{1}{307}$, the measures at the equator being considered as unity; also the increase in the number of vibrations of an invariable pendulum beating seconds at the equator on proceeding towards the pole. This merely shows the relative values of the quantities therein stated.

The second and third tables are from MENDOZA's Tables for Navigation and Nautical Astronomy. And the fourth is from the very valuable Introduction to Practical Astronomy by Dr. Pearson, where it is stated to be computed from a Formula given by Lieut.-Col. Lambton in the Asiatic Researches, vol. xii.

The tables are constructed from different values of the earth's compression at the poles. The uncertainty of this important element, in all questions of geography and astronomy, is an inconvenience which cannot yet be got rid of.

In Tables II. and III., the dimensions of the degrees of latitude and longitude are given in minutes of the equator. To change these into feet or fathoms, we must know the number of them in a degree of the equator.

According to Puissant and Svanberg, the equatorial degree, or 60 geographical miles, is 60,847 fathoms.

Cagnoli has assumed = 60,893 fathoms.

Lieut.-Col. Lambton reckoned it to be 60,857 fathoms.

General Mudge concluded it to be 60,845 fathoms.

Mr. Baily, as an accompaniment to his table (Table I.), assumes the equatorial diameter of the earth to be 7924 miles, and the polar = 7916 miles. A degree of longitude at the equator will, on this supposition, be 69.15 miles, = 60,852 fathoms, = 365,110 feet: so one second of time, or fifteen seconds of a degree of longitude, will be 1521 feet.

Table IV. gives the measure of each degree of latitude and longitude in fathoms.

TABLE I.

Compression = $\frac{1}{300}$			Compression = $\frac{1}{307}$

CHAP. XX.

DETERMINATION OF LATITUDE AND LONGITUDE.

571. *There are three important problems in geography which require for their solution the doctrines of astronomy.* The first requires to find the direction of the meridian at any point of the earth's surface; the second, to find the latitude of any place; and the third, to find the longitude.

PROBLEM I. *To determine the Meridian, or to draw a Meridian Line.*

572. *This problem, like many others in practical astronomy, admits of a comparatively easy solution, if no great degree of accuracy is required; but to obtain a very accurate result, much care, and instruments of the most perfect construction, are indispensable.*

573. *The general principle of the solution is the fact, that the celestial bodies which do not sensibly change their declination in the course of a day, have the same apparent altitude at equal intervals of time before and after passing the meridian: also, that their altitude is greatest or least when in the plane of the meridian; that is, when they are due south or due north.*

574. *About the time of the summer and winter solstice, the sun changes his declination very little in the course of a day: and hence it happens that the shadow of an upright rod or gnomon is almost exactly of the same length when the sun is at equal distances from the meridian.* To determine the position of the meridian, then, let a number of concentric circles be described on a horizontal plane, and let a wire or rod be placed directly over their common centre, and perpendicular to the plane; and, the sun shining on the plane, let the two points in which the extremity of the shadow of the wire crosses each circle be exactly noted. Then, through any point of the plane which is at equal distances, from each pair of intersections draw a straight line through the centre of the circle; and this will be in the plane of the meridian, or will be a *meridian line*. It is easy to see that one circle, and one pair of intersections of the path of the extremity of the shadow and the circle, would be sufficient: but several circles will fulfil the object with greater accuracy and more certainty; because a mean position of the meridian line may be found among all the results; and besides, one of a pair, or both, may be lost by clouds intercepting the light of the sun.

575. *The imperfection of this method of finding the meridian arises from the indistinctness of the termination of the shadow of the upright wire, and from the change of the sun's declination between the observations.* There is, however, another as simple and exact as can be expected, without the assistance of a telescope. It is known that the pole star and the star Alioth, or ϵ of the Great Bear, pass the meridian within about nine minutes of each other. If, therefore, we suspend two plummets by threads to the ends of a rod which turns horizontally on a pivot, and by moving the rod, keep the two plumb-lines exactly between the eye and Alioth when near the meridian, then, at the moment when the pole star is also seen along the two plumb-lines, the two stars and the plumb-lines will be all nearly in the plane of the meridian. To keep the plumb-lines steady in the vertical plane, the plummets may hang in vessels filled with water.

576. *If we could determine the position of a star when its altitude is greatest or least, we would then have a point of the heavens in the plane of the meridian: but that position cannot be found with certainty, because the change of altitude is imperceptible to a sensible distance on each side of the meridian.*

577. *The exact determination of the meridian requires the aid of the telescope, a well-regulated clock, and an instrument for determining the altitude of the sun or a star: Hadley's sextant, or a reflecting circle, are the proper instruments for this purpose.* By the sextant we can determine two instants of time when the star has the same altitude; the clock will give the interval of time between them: and half this interval will be the time between each observation and the passage of the star over the meridian. If we next day note the time by the clock when the star again attains that altitude, and add to that time the above-mentioned half interval, we shall have the time by the clock when the star will be on the meridian. If at that instant a telescope, moveable in a vertical plane, be directed to the star, so that in passing the meridian the star may be in the axis of the telescope, the position of the plane of the meridian will be obtained: and if the telescope be fixed to a horizontal axis which is perpendicular to that plane, it will have a vertical motion in the plane of the meridian, and will be what is called a *transit instrument*. By this instrument the exact instant when any celestial phenomenon is on the meridian is known. It is, therefore, one of the most essential instruments in an observatory.

578. *In a variable climate like Britain, it may happen that the observations necessary to determine the meridian may be interrupted by cloudy weather.* This, however, is an inconvenience to which all astronomical observations are liable. It must also be observed, that a single set of observations will not give so perfect a result as a considerable number of sets, from which a mean may be deduced.

579. *If the celestial object change its position otherwise than by the diurnal motions of the earth, as happens when it is the sun, still the problem may be resolved, as has been explained, by making allowance for the change of position, by applying the principles of spherical trigonometry to the laws of the motion.*

PROBLEM II. *To determine the Latitude.*

580. *In treating of the doctrine of the sphere, it has been shown (§ 268.) that the distance of the pole of the world (that is, the point of the heavens about which all the stars turn) from the horizon of any place is equal to its latitude. Now, in the course of twenty-four hours, every star passes the meridian twice, at equal distances from the pole, and on opposite sides of it. When the star passes the meridian below the pole, — that is, between the pole and the horizon, — its altitude is the *least* possible; and when it crosses the meridian above the pole, or between the pole and the south point of the horizon, its distance from the north point of the horizon will be the *greatest* possible. If, therefore, with a suitable instrument, (a quadrant for instance,) we take the star's altitude when it is least, and also when it is greatest, and correct these for refraction, it is manifest that half their sum will be the latitude of the place where the observations were made.*

581. *We have supposed the star to pass the meridian between the pole and the zenith, and then its greatest altitude will be its distance from the north point of the horizon: but it may pass to the south of the zenith, and then its altitude, reckoned from the south, must be subtracted from 180° to get its distance from the north point of the horizon; and half the sum of the two distances, as before, will be the latitude.*

582. *Any one star that never sets, the pole star for instance, will serve to determine the latitude: but it will be proper, if circumstances allow, to observe various stars, and the mean of all the observations may be expected to be more correct than a single pair.*

583. *If, instead of the greatest and least altitudes of a star, its greatest and least distances from the zenith be found, then half their sum will be the *complement* of the latitude; that is, the difference between the latitude and ninety degrees.*

584. *For example, by observations made on the pole star at Dublin Observatory it was found that*

Its greatest zenith distance, corrected for refraction, was	-	38° 19' 43".11
Least	-	34 53 49.55
The sum	-	73 13 32.66
Half the sum, or co-latitude of observatory	-	36 36 46.33
The latitude	-	53 23 13.67

585. *When the latitude of one place is known, the latitude of another place may be found by observing with a quadrant, or other suitable instrument, the zenith distances of any star at both places. The difference of these zenith distances, when corrected for refraction, will be the difference of latitude of the two places.*

586. *Thus, for example, to determine the difference between the latitudes of Greenwich Observatory and Dunnose in the Isle of Wight, it was found that*

At Dunnose the z. d. of β Draconis was	-	1° 50' 5".24
And at Greenwich	-	0 58 33.13
Difference of latitude	-	0 51 32.11
The latitude of Greenwich was known to be	-	51 28 30.5
The latitude of Dunnose is	-	50 37 8.39

587. *The navigator has daily occasion to determine his latitude at sea. For this purpose, he finds the sun's zenith distance, or its altitude at noon, by Hadley's sextant. The Nautical Almanac gives him the sun's declination, or distance from the equator at the time he makes his observation: the sum or difference of these is his latitude, according as the ship and the sun are on the same or opposite sides of the equator.*

588. *Ex. On July 24. 1783, at a place in longitude 54° ($3^h 36^m$) west of Greenwich, the altitude of the sun's lower limb, when cleared from refraction and parallax, was observed by a sextant to be $59^\circ 15' 30''$. By the Nautical Almanac, the sun's semidiameter was $15' 48''$, and his declination at the time of noon in that longitude $19^\circ 51' N$. The calculation for the latitude will stand thus: —*

Altitude of sun's lower limb	-	-	-	-	59° 15' 30"
Add sun's semidiameter	-	-	-	-	15 48
Subtract altitude of sun's centre	-	-	-	-	59 31 18
From	-	-	-	-	90 0 0
To sun's zenith distance	-	-	-	-	30 28 42
Add sun's declination	-	-	-	-	19 51 0
The latitude of the place is	-	-	-	-	50 19 42

589. *The navigator cannot always obtain an observation of the sun or a star when on the meridian.* He may, however, be able to observe two altitudes out of the meridian, and the interval of time between them. With these data, and the aid of spherical trigonometry and the Nautical Almanac, he may find his latitude by rules given by writers on navigation and astronomy. It is, in general, by one or other of these methods that the recorded latitudes of all places have been obtained, and arranged in a table for the use of the geographer and navigator.

PROBLEM III. *To determine the Longitude.*

590. *The interval of time between two successive passages of the sun over the meridian of any place is twenty-four hours.* If, therefore, we suppose a number of meridians to be drawn at equal intervals, — that is, to form successively with each other equal angles at the poles, — then, in the course of twenty-four hours, each of these meridians (supposing their planes produced) will pass through the sun. Therefore twenty-four hours of mean solar time will correspond to 360 degrees of longitude; for the whole scale of longitude must be contained between the eastern and western sides of the meridian of the same place. At places situated on the meridian opposite that on which the sun was at 0^h, or, in civil reckoning, at 12 at noon, the time would be 12^h, or 12 at night; and 12^h would correspond to 180 degrees of longitude. At places situated on the meridian at right angles to the former, the time would be 6^h or 18^h, or, in civil reckoning, six in the morning or six in the evening; and, accordingly, six hours and eighteen hours of mean solar time will correspond to 90° or 270° of longitude; and so on for intermediate meridians.

591. *The selection of a meridian, from which the longitude is to be reckoned, is entirely arbitrary.* The English take the meridian passing through Greenwich Observatory for the first meridian, and reckon its longitude to be 0° or 0^h. The first meridian of the French is that which passes through the observatory of Paris. An interval of 9^m 21^s elapses between the passages of the sun over the meridians of Paris and Greenwich: the longitude of Paris Observatory is, therefore, by English geographers, accounted to be 9^m 21^s east, in time; or in degrees, 2° 20' 15".

592. *Since it is noon at all places on the meridian of Greenwich from pole to pole at the same instant, it will be an hour past noon, or 1^h, at all places on the meridian 15° to the east of that of Greenwich; and two hours past noon, or 2^h, at all places on the meridian 30° east from that of Greenwich; and so on.* On the other hand, it will want an hour to noon, or will be 11^h, at all places on the meridian 15° west from that of Greenwich; and it will be two hours before noon, or 10^h, at places on the meridian 30° west from that of Greenwich; and so on, reckoning an hour, or sixty minutes of time, to correspond to fifteen degrees, and four minutes of time to one degree.

593. *Since it appears that all places on the same meridian have noon, or any assumed hour, at the same instant, and that the instant of noon is different at places on different meridians, — being earlier or later on meridians having west longitude, according as they are nearer to or farther from the first meridian, and the reverse on meridians having east longitude; and moreover, that the difference between the time of noon on two meridians is proportional to the difference of their longitude, and therefore a measure of that difference; it follows that if, knowing the hour of the day at any place, we can at the same instant by any means know the hour at a place on any other meridian, then we can determine the difference of longitude between the meridians: for it will be the difference between the times of the day, as estimated on the two meridians, reckoned in hours, minutes, &c.; and this may be converted into degrees, minutes, and seconds, by reckoning fifteen degrees to an hour, and proportionally for minutes and seconds of time.*

594. *The practical methods of determining the longitude are the following: —*

1. *By a Chronometer or Time-keeper.*

Let us suppose that a traveller departs from any place, (St. Paul's, London, for example,) and carries with him a watch regulated to mean solar time, and which indicates 12^h at the instant of *mean noon* at London: then, supposing the watch to go with perfect regularity, if he go to Edinburgh, and compare the estimated solar time there with that shown by

his watch, he will find that they differ by twelve minutes twenty-one seconds; so that when it is 12^h at Edinburgh Observatory, it will be $12^h 12^m 21^s$ by his watch. He may therefore conclude, that the difference of longitude between London and Edinburgh is $12^m 21^s$ west; and since St. Paul's is twenty-three seconds of time west from Greenwich, the longitude of Edinburgh Observatory is $12^m 44^s$ west, which corresponds to $3^\circ 11'$. If, leaving London, he had gone to Paris, he would there have found the estimated time to be $9^m 44^s$ earlier than that shown by his watch: hence the difference between the meridians of London and Paris is $9^m 44^s$, and the longitude of Paris (from Greenwich) $9^m 21^s$ east.

595. *In the same way the navigator at sea may determine his longitude by a good chronometer.* He can determine the hour of the day by the sun's altitude, and the principles of spherical trigonometry. Or he may take equal altitudes, noting the times; the middle point of time between them will be the instant of noon, as shown by the watch: he must, however, make a correction for the change of the sun's declination, and the distance run by the ship in the interval. Supposing now the chronometer to have been set to the true time at the port from whence he sailed, and to have gone uniformly with a small known daily acceleration or retardation, called its *rate*; this correction being applied, he will have the time at the port corresponding to his observed time of noon, and their difference will be the longitude of the ship eastward or westward from the meridian whence she sailed.

596. *The longitude of any point on the earth, either at sea or on land, may be determined by a good chronometer;* in the latter case, however, the jolting it must suffer by carriage will disturb its motion, and render the result sought uncertain. At sea, the mode of transport is not so liable to sudden jerks; and, therefore, the chronometer may be expected to go with more regularity. If several be employed, considerable accuracy may be obtained. The Board of Admiralty sent ten or twelve chronometers from Greenwich to Falmouth, and thence in a vessel to Madeira, and in this way determined the longitude of Funchal from a mean of their results.

597. *The facility of this mode of determining the longitude makes perfection in the construction of chronometers an object of high importance in a maritime nation like Britain.* It was, therefore, for many years encouraged by acts of parliament offering high rewards for prescribed degrees of excellence. These, however, are now repealed; but the government has not lost sight of this important subject.

2. The Longitude by Eclipses of Jupiter's Satellites.

598. *If a celestial phenomenon can be seen at the same absolute instant of time in two different places of the earth, this appearance gives the means of determining the difference of their longitudes;* for if the phenomenon be seen at both places, and the times, according to their reckoning, be noted, it is manifest that their difference will be the difference of longitude, in time, of the two places.

599. *Now the eclipses of Jupiter's moons are phenomena of this kind.* They may be seen, almost at the same instant, every where in the hemisphere in which Jupiter is visible: and such is the perfection of astronomy, that the times at which they will happen can be predicted with considerable accuracy. These are computed according to Greenwich time, and published, along with various other matters, in the Nautical Almanac several years before they happen, for the benefit of travellers. This method of finding the longitude can, however, only be applied on land; for at sea the rolling of the ship makes it next to impossible to direct a telescope so steadily to Jupiter as to view the eclipse of a satellite.

600. *Example.* — Suppose an immersion of the first satellite should be observed at the Cape of Good Hope April 16. 1805, at $13^h 25^m 35^s$ mean time; the predicted time given by the Ephemeris being $12^h 12^m 2^s$ at Greenwich. Here the difference is $1^h 13^m 33^s$; whence the longitude of the Cape should be $18^\circ 29' 15''$ east of Greenwich.

601. *In this example, the observed time at the Cape is compared with the computed time of the eclipse at Greenwich.* If, instead of this, the observed time at Greenwich had been used, greater accuracy might have been expected.

602. *This method is easy, and therefore much practised;* but it is liable to uncertainty: for two observers in the same room, but using different telescopes, will sometimes differ in noting the time of an eclipse of the first satellite by as much as fifteen or twenty seconds. Delambre thinks that the time of an eclipse of the fourth satellite may be doubtful to the amount of four minutes.

3. Longitude by an Eclipse of the Moon.

603. *An eclipse of the moon has exactly the same appearance, at the same instant, wherever seen;* but it is impossible to be quite sure, by observation, of the exact time of their beginning or end, because of the penumbra which bounds the earth's shadow. The results to be obtained from them are therefore uncertain, to perhaps two minutes of time; and therefore only to be regarded as approximations to the truth.

604. *Example.* — An eclipse of the moon was observed Aug. 28. 1729, by the astronomer Cassini at Paris, and by Mr. Stephenson at Barbadoes.

At Paris, Imm. $\gg$	-	12 ^h 19 ^m 13 ^s	Emer. $\gg$	-	13 ^h 59 ^m
At Barbadoes, Imm. $\gg$		8 11 0	Emer. $\gg$	-	9 51
		4 8 13			4 8

By the mean of the two, the difference of longitude is 4^h 8^m 6^s.5; that is, Barbadoes is 62° 1' 30" west of Paris.

4. Longitude by Lunar Distances, or by Occultations of Stars by the Moon.

605. The moon is, of all the celestial bodies, the most convenient for determining the longitude, because of the greater quickness of her apparent motion among the stars. She makes the complete circuit of the heavens in 27^d 7^h 43^m 4^s.7 (this is her mean sidereal revolution): therefore she changes her place among the stars more than half a degree, or her own apparent diameter, in an hour; so that in two minutes of time she passes over one minute of a degree. This, or even its half, is quite a measurable quantity by a good sextant.

606. By the theory of the moon's motion, her place among the stars is known at any time: that is, knowing the time of the day at Greenwich, the place of the moon is known; and, on the other hand, knowing the place of the moon, the time at Greenwich is known. The Nautical Almanac gives the distances of the moon's centre from the sun, and some of the brighter stars, as it would be seen from the earth's centre, for every third hour of the day, Greenwich time. If, therefore, the Almanac show that the moon, considered as seen from the earth's centre, will be 10° from a certain fixed star at six o'clock in the evening at Greenwich; and we make an observation at a distant place, and find that the moon's distance from the same star, reduced by computation to what it would be if seen at the earth's centre, is 10°, we immediately conclude that at that instant it is six o'clock at Greenwich. Thus the moon, with the brighter fixed stars near her path, serve the purpose of a chronometer.

607. To determine the longitude in this way, one observer measures the moon's distance from the sun or a bright star (one of those in the Ephemeris); another observer at the same time finds the altitudes of the moon and star; and a third should observe the exact time by a chronometer or good watch at which the observations were made. These observations, corrected for refraction, give data for finding what would be the apparent place of the moon in the heavens, if it could be seen from the centre of the earth at that time. The Nautical Almanac enables the observer to find the hour at Greenwich, when the position of the moon in the heavens was such as he observed it, and the interval between the Greenwich time and his own gives him his longitude.

608. This method of finding the longitude is commonly practised in the service of the East India Company, and in the navy. By it the longitude may be generally known to within twenty miles, and very often much nearer. This, although less accurate than the latitude, is yet an invaluable acquisition to the navigator. A striking proof how much it may be depended on has been given by a distinguished navigator (Capt. Basil Hall, R. N.). After a voyage of 8000 miles, occupying eighty-nine days, he arrived off Rio de Janeiro, having passed through the Pacific Ocean, rounded Cape Horn, and crossed the South Atlantic, without making any land. When within a week's sail of Rio, he set about determining, by lunar observations, the ship's course and place at a determinate moment; and having found this, within from five to ten miles, he trusted to the ordinary and more compendious way of finding his position, such as is used in short trips, for the remainder of his voyage. When he arrived within fifteen or twenty miles of the coast (according to his estimation), he hove to at four in the morning, waiting for day-break. He then proceeded, although the weather was hazy; but about eight it became so foggy that he did not like to stand in farther. The fog suddenly cleared off, and then he had the satisfaction to see the Great Sugar-loaf Rock, which stands on one side of the harbour, so nearly right a-head, that he had not to alter his course above a point in order to hit the entrance of Rio.

609. Occultations of stars by the moon serve exactly the same purpose as a distance of the moon from a star: these, however, are not so generally observed at sea as on land. They give the distance of the moon from the star with almost perfect accuracy, and therefore are an excellent method of determining the longitude. When an occultation has been observed, we can by the lunar tables or the Nautical Almanac, which is a species of lunar and solar tables, compute the distance between the centre of the moon and star as it would appear at the earth's centre at the moment the occultation was observed, provided we know the longitude of the place where the observation was made: but this longitude is the very thing we want; therefore we cannot proceed by a direct process. However, we may know the longitude nearly by some other means; an eclipse of one of Jupiter's satellites, for

example. With this, as if it were the true longitude, we may calculate the apparent distance between the star and centre of the moon reduced to the earth's centre at the time the occultation was seen. If the longitude had been correctly assumed, this would have been exactly the moon's semidiameter; but it will differ more or less, according to the magnitude of the error we have made in the assumed longitude. There will, however, be such a determinate connection between the error of the longitude and the difference between the moon's semidiameter and computed distance of the star and moon's centre, that the one will be deducible from the other by calculation. In this way, then, the error may be estimated, and a nearer approximation to the longitude obtained; and a repetition of the process will give a still more correct result.

5. Longitude by the Transit of the Moon over the Meridian.

610. Let T be the time by the clock when the moon is observed on the meridian of any place, t the time of transit of a known fixed star, $24 + x$ the interval between two successive transits of the same star: then $24 + x : T - t :: 360^\circ$: difference of right ascension of the moon and star at the instant the moon was on the meridian; to which adding the known right ascension of the star, the right ascension (A) of the moon when on the meridian is determined. Now the moon's right ascension when on the meridian of Greenwich is given in the Nautical Almanac for every day of the year, from whence the daily increment of her right ascension may be determined: let, therefore, a be the moon's right ascension when on the meridian of Greenwich, E the increment of right ascension in the time between two successive transits over the same meridian; then, considering the change of right ascension as uniform,

$$E : a - A :: 360^\circ : \text{the required longitude.}$$

6. Longitude by Signals.

611. *The most accurate way of determining small differences of longitude* is by signals made on the earth's surface. A rocket fired from an elevated spot on a clear night may be seen distinctly with a telescope at the distance of twenty or thirty miles: therefore, by observing the times at which the same explosion is seen at two places, the difference of longitude of the places may be found.

612. *The same method will apply to places at any distance*, if they be connected by a chain of stations sufficiently near to each other to admit of a rocket to be seen from every two adjoining stations. The difference of longitude between Greenwich and Paris was determined in 1825 in this way. Rockets were exploded at Wrotham, and seen simultaneously at Greenwich and Fairlight Down: also at La Canche on the French coast, which were seen at Fairlight and Ligniers; and at Mont Javoult, which were observed at Ligniers and Paris.

613. *In the same way the difference of longitude* between Geneva and Milan has been determined by signals made by illumination on the tops of intermediate mountains.

614. *The intensely brilliant light which Lieutenant Drummond*, of the Royal Engineers, has proposed for light-houses, and which is produced by placing a ball of lime, about the size of a pea, in a flame supported by oxygen gas, may be employed in determining differences of longitude. We believe that, in favourable weather, this light exhibited on the top of Ben Lomond may be seen at the same time at Edinburgh and in Ireland: indeed, we know that it has actually been seen in the north of Ireland. Here, then, we have the means of determining with great exactness the difference between the longitude of Dublin and Edinburgh.

7. Longitude by Triangulation.

615. *The trigonometrical survey of Britain* has determined the longitude of all the principal points on the coast, as well as the mountains and cities in the interior, particularly in England. At present the survey is suspended in Britain, but is going on in Ireland. When this is completed, the British survey will doubtless be resumed, and the geography of the northern part of the island made as perfect in its minute details as the southern, which, from its proximity to the Continent, is more necessary to be known in preparing plans of national defence.

CHAP. XXI.

REPRESENTATION OF THE EARTH.

616. *The most natural and correct representation* which can be given of the geographical divisions of the earth's surface is that which is made on a sphere or globe. In this way the different countries may be truly delineated, so as to exhibit perfectly to the eye their relative position, their magnitude, and boundaries; and by such a representation of the earth, all the problems in geography may be resolved with elegance and facility.

617. *But although the surface of a solid* having the exact figure of the earth, or differing but little from it, affords in theory the most complete and the only perfect representation of

any considerable tract of country, yet there is a limit in practice to this precious advantage. A globe of a moderate size serves very well to give a distinct notion of the figure, the magnitude, the position, and general features of the great continents and islands: but the largest globe that can conveniently be constructed is insufficient for minute details; and then we must have recourse to the more simple, although less perfect, representations of MAPS.

618. *It is impossible to represent on a plane a large extent of the earth's surface, so that the distances of places in the plane map shall have to each other precisely the same proportion as their distances on the globe.* To obviate this difficulty, geographers have had recourse to different methods of representing portions of the globe on a plane.

619. *By one method the countries are represented by the rules of perspective, as they would appear to an eye that should view them on the surface of a sphere from a given point.* The different positions which may be assumed for the point from which the sphere is viewed give rise to different *projections*, which all answer very well when the surface to be represented is of small extent, and the point of view, or *projecting point*, is nearly over its centre. However, when the surface is of great extent, a whole hemisphere for instance, those places which lie near the border of the projection are in them all much distorted.

620. *According to another method, the spherical surface to be represented is supposed to be a cone whose vertex is somewhere in the polar axis produced, and its curved surface either touches the sphere at the middle parallel of the map, or falls within the sphere at the middle parallel, and without it at the extreme parallels.* The surface of the cone is then supposed to be extended into a plane. This way of constructing maps is called the method of *development*.

621. *There are other mathematical hypotheses according to which maps are delineated, and one in particular by which marine charts are constructed.* In this, the parallels of latitude and circles of longitude are all represented by straight lines (that is, a line making always the same angle with the meridian), and the course of a ship sailing always on the same rhomb is also a straight line. A representation of the earth in this way is commonly called *Mercator's chart*, although the invention is due to an English mathematician, Edward Wright. Charts of this construction are of great importance in navigation.

I. CONSTRUCTION OF MAPS BY PROJECTION.

622. *There are two projections of the sphere by which portions of its surface may be truly delineated by the rules of perspective: the ORTHOGRAPHIC and the STEREOGRAPHIC.* In each, the plane on which the projection is made is called the *plane of projection*.

1. ORTHOGRAPHIC PROJECTION.

623. *To project any point in space orthographically on a plane, a perpendicular is to be drawn from the point on the plane and the bottom of the perpendicular; that is, the point in which it meets the plane is the orthographic projection of the point.*

624. *The orthographic projection of a line of any kind on a plane is found by supposing perpendiculars to be drawn from every point in the line, and that line on the plane which passes through the bottom of all the perpendiculars is the orthographic projection of the proposed line.*

625. *It is easy to see that the orthographic projection of a straight line must be a straight line, because the perpendiculars drawn from every point in it to the plane of projection will all lie in a plane, and the common section of two planes is a straight line.* It is also apparent that the projection of a rectilineal figure will be a rectilineal figure.

626. *If a circle be parallel to the plane of projection, its orthographic projection or representation will be a circle: for the perpendiculars supposed to be drawn from every point in the circle to the plane of projection will all be on the curve surface of a cylinder, and they may be considered as constituting that surface.* The circle and its projection will be the top and bottom of the cylinder; and since they are parallel, they will be alike and equal.

627. *If the plane in which a circle lies be perpendicular to the plane of projection, its projection will manifestly be a straight line, which will be equal in length to the diameter; and the projection of any arc reckoned from the extremities of the diameter will be projected into its versed sine: also the complement of the arc, or what it wants of ninety degrees, will be projected into its sine.*

628. *But if a circle be in a plane which is neither parallel nor perpendicular to the plane of projection, then its projection will neither be a circle nor a straight line; it will be an oval figure.* The bounding line will be an *ellipse*, a curve formed by cutting a cylinder by a plane oblique to its axis; and it is also one of the *conic sections*.

629. *An exact notion may be formed of the orthographic projection of any line or figure by holding it in the light of the sun, and observing its shadow formed on a plane which is perpendicular to the direction of the solar rays.* The rays which pass close to the figure are the perpendiculars to the plane, and the shadow is the projection of the figure.

630. *The plans and sections by which artificers execute different constructions are no other than orthographic projections of the things to be constructed; with these all workmen are familiar.*

631. The orthographic projection of any object, — the *terrestrial globe*, for example, — with all its circles, and the continents and islands on its surface, is *nearly* the representation or picture which an artist would delineate on a plane surface if he meant to represent the globe at a great distance from the eye; and it is *exactly* the appearance which the globe would have, supposing an eye could view it at an infinite distance.

632. From the nature of this projection, it appears that the orthographic representation of half the surface of the globe will show nearly the true figure and proportions of countries about the middle; that is, directly opposite to the supposed position of the eye: but, towards the extremities of the map, the graphic representations of places will imperfectly exhibit their true figure and position. For this reason it is seldom employed in geography, although its use is frequent in astronomy.

(A.) To project the Sphere orthographically on the Plane of the Equator.

633. About any point, C, as a centre (fig. 45.), with any radius, C A, describe a circle

B A 90 to represent the equator. Draw two diameters, A C 180, B C 90, perpendicular to each other: these will be the projections of meridians distant 90° from each other, and C will be the projection of the pole.

634. Divide each quadrant into six equal parts, and let A 15, 15 30 be two of these; draw diameters through 15 and 30, and these will be the projections of meridians 15° and 30° from A C 180; and, in this way, meridians dividing the equator into twenty-four equal parts may be represented. Of these, any one, C A, may be assumed as the first meridian.

635. To project the parallels of latitude: divide A B, one of the quadrants, into nine equal parts; let 80, 70, 60 be the three of these points of division adjoining to B: draw perpendiculars from these, and all the other points on the radius A C meeting it in 80, 70, 60, &c. About C as a centre at the distances C 80, C 70, C 60, &c. describe circles, and these will be the projections of parallels of latitude at the distance of ten degrees.

636. The polar circles and tropics may be found by laying off an arc of $23\frac{1}{2}^\circ$ from A towards B, and from B towards A, and drawing perpendiculars from the points thus determined on C A, circles described about C, through the bottoms of the perpendiculars, will be the projections of the polar circle and tropic. In this way, the projection may be completed.

637. It is easy to see that the regions within the polar circle may be represented by this projection so as to give a tolerable notion of their position and magnitude, judging by the eye; but that the appearance of the equatorial regions will be altogether distorted.

(B.) To project the Sphere orthographically on the Plane of the Meridian.

638. Describe any circle, N E S Q (fig. 46.), to represent the meridian, and draw two

diameters, E C Q, N C S, perpendicular to each other; the former may be taken as the projection of the equator, and then the latter will represent a meridian 90° from the meridian N E S.

639. To represent other meridians: divide a quadrant S E into six equal parts, as at 15, 30, &c.; from these points of division draw perpendiculars 15 a, 30 b, &c. on E Q. Describe ellipses N a S, N b S, having a common transverse axis N S, and the lines C a, C b, &c. for their semiconjugate axes; and these will be the projections of meridians which pass through every fifteenth degree of the equator. Or, by dividing E S into nine equal parts, they may be made to pass through every tenth degree.

640. For the parallels of latitude: divide the quadrants E N, N Q each into nine equal parts at 10, 20, 30, &c.; join the corresponding numbers by straight lines, and these will be the projections of parallels of latitude at

distances of 10° , 20° , 30° , &c. from the equator. The tropics and polar circles are to be drawn in the same way; the former at $23\frac{1}{2}^\circ$ on each side of the equator, and the latter $23\frac{1}{2}^\circ$ from the poles.

641. In this projection, the polar regions, and all places near the meridian N E S Q, are very much distorted in appearance to the eye: it is only towards the centre that there is any considerable resemblance of a projected portion of the earth's surface to its appearance on a globe.

2. STEREOGRAPHIC PROJECTION.

642. In the stereographic projection, the eye is supposed to be situated at a point in the surface of the sphere, and the plane on which the projection is to be made is the plane of that great circle, which is every where 90° distant from the position of the eye: hence it must be evident that the eye can see only the inside or concave surface; however, we may suppose the sphere to be transparent, and its various circles, and the islands, continents, &c. delineated on its surface to be seen through it. If we now conceive a line to be drawn from the eye to any point on the concave surface, the point in which that line cuts the plane of projection will be the projection of the point on the spherical surface.

643. To illustrate what has been said, let E A C B (fig. 47.) be a great circle of the sphere, $p q r s$ a plane passing through its centre, and perpendicular to the plane of the great circle; let C E be a diameter of the sphere perpendicular to the plane; then assuming $p q r s$ as the plane of projection, E, one end of that diameter, may be taken as the place of the eye or projecting point. If, now, straight lines E A, E B, E C, E D, &c. be drawn to A, B, C, D, any points on the surface of the sphere, the points a, b, c, d , &c. in which these lines meet the plane $p r$, will be the projections of the corresponding points on the surface of the sphere. Let A D B be any circle of the sphere: conceive a straight line to be drawn from E, the place of the eye, to D, any point in the circumference. If D, the end of this line, be now carried

round the circle, supposing it always to pass through the fixed point E, the line will generate the surface of a cone whose base is the circle, and vertex the place of the eye; and the curve line $a d b$, which is the common section of the plane $p r$, and the surface of the cone will be the projection of the circle.

644. It will now be sufficiently obvious,

1. That every circle which passes through the eye will be projected into or represented by a straight line on the plane of projection.
2. That every circle whose plane is parallel to the plane of the circle will be projected into a circle.

645. These two properties hold true wherever the eye be situated. The assumption, however, that it is in the surface of the sphere gives rise to geometrical properties which are peculiar to this projection, and which by their simplicity and elegance give it great value.

646. One geometrical property is this: whatever be the position of the circle A D B (or base of the cone) on the surface of the sphere, the portion of the cone between the projecting point E and the plane of projection $p r$ is always similar to the whole cone. If the plane of the base be parallel to the plane of projection, the truth of this proposition is obvious; but writers on geometry prove, that when it is oblique, still the cones whose bases are A D B and $a d b$, and common vertex E, are similar; only they have contrary positions. From the similarity of the whole cone to the part cut off, it follows that,

3. In the stereographical projection of the sphere, the representation of any circle that does not pass through the eye will always be a circle.

647. There is another proposition demonstrated by writers on spherical geometry which is of great importance in this projection; viz. if two straight lines be drawn from any point on the surface of the sphere to touch it in that point, their representation on the plane of projection will contain an angle exactly equal to the angle contained by the lines themselves. Since straight lines touching the surface of a sphere at any point may be regarded as tangents to any circles of the sphere passing through that point, we have this other remarkable property: —

4. The angle made on the surface of the sphere by two circles which cut each other, and the angle made by circles which are their representations, are in all cases equal.

648. This projection is extremely convenient in practice, because a circle may be easily described when three points in its circumference are given, or when two points and its radius are known; also, the property of lines making angles at their intersection on the surface of the sphere equal to those formed by their projections, is of great value in the

representation of the surface of the sphere on a plane. Moreover, the contraction of the map towards the extremities of an hemisphere is not so great as in the orthographical projection; on all these accounts, the stereographical projection deserves a preference.

649. *Supposing E to be the projecting point, or place of the eye, and pr the plane of projection, let C be the point of the sphere opposite to E, and therefore 90° every where from the circle, which is the common section of the sphere and plane of projection; it is evident that any arc, A C, of a great circle passing through C and E will be projected into a straight line ac : now, this line is manifestly the tangent of the angle A E C to the radius E c, and the measure of this angle is half the arc A C.*

5. Hence it follows, that if a great circle pass through the projecting point, any arc of that circle, reckoned from the opposite point on the sphere, is projected into a straight line passing through the centre, and equal to the tangent of that arc.

(A.) *To project the Sphere stereographically on the Plane of the Equator.*

650. *Describe a circle, A B D (fig. 48.), to represent the equator, and draw any diameter*

A C D, and a radius C B perpendicular to A D. Supposing now that the parallels of latitude to every tenth degree are to be represented in the map, divide A B, a quadrant of the circle, into nine equal parts, as at the points 10, 20, 30, &c. and draw straight lines from the points of division to D, the extremity of the diameter A C D, meeting the radius B C in the points 10, 20, 30, &c. Then, about the centre C describe circles to pass through the points 10, 20, 30, &c., and these will represent the parallels of 10, 20, 30, &c. degrees of latitude. In this way, all the parallels of latitude may be found, as also the tropic and polar circle, by laying off arcs of $23\frac{1}{2}^\circ$ and $66\frac{1}{2}^\circ$ from B towards A.

651. *Next divide the circumference of the circle into 24 equal parts, and draw radii from the centre to the points of division.*

These will represent the meridians which differ in longitude by one hour.

(B.) *To project the Sphere stereographically on the Plane of a Meridian.*

652. *Describe any circle, N Q S E (fig. 49.), to represent the meridian on which the pro-*

jection is to be made; which should be so chosen as to include nearly one of the continents, — the eastern, for instance: this will be accomplished if N E S be the meridian 20° west from London. Draw the diameter N C S, which will represent the meridian that passes through the projecting point, and therefore is perpendicular to the plane of projection. Then N will represent the north, and S the south pole: draw another diameter, E C Q, which will represent the equator.

653. *Since, by the nature of the projection, all the meridians will be represented by circles which pass through the poles N, S, it will be sufficient if we determine the points in which they cut the equator: we shall suppose the meridians to pass through every tenth degree of longitude: the points where they cut the equator will be found by dividing one of the quadrantal arcs, N Q, into nine equal parts, as*

at 10, 20, 30, &c., and drawing straight lines from S to the points of division, meeting C Q in 1, 2, 3, &c. Then, a circle described through the points N 1 S will represent the meridian which cuts the equator 10° from Q, and a circle through N 2 S will be the meridian that cuts the equator 20° from Q. The remaining meridians N 3 S, &c. will be determined exactly in the same way; and it appears from the construction, that the centres of the circles will be in the diameter E Q and its prolongation, and their distances from the centre will be the tangents of 10° , 20° , &c.; viz. the inclination of the circles to the plane of the primitive; also, that their radii will be the secants of the same inclinations.

654. To describe the parallels of latitude, divide the four quadrants each into nine equal parts, as at 80, 70, 60, &c., and draw straight lines from E, one end of the diameter E Q, to the points of division, meeting N S in 8, 7, 6, &c. Then circles described through 80, 8, 80; 70, 7, 70, &c., will represent the parallels of 80° , 70° , &c. The centres of all the circles will be in the line N S, and distant from it by the secants of the distances of the parallels from the pole: also, the radii will be the tangents of the same distances. The polar circles and tropics being described by the same rules at the distances $23\frac{1}{2}^\circ$ and $66\frac{1}{2}^\circ$ from the poles, the projection will be completed.

(C.) To project the Sphere stereographically on the Plane of the Horizon for a given Latitude.

655. In this projection, the eye is supposed to be in the nadir of the place for which the projection is made.

On C (fig. 50.) and C (fig. 51.) as centres with any radius, describe circles W N E S, W' N' E' S', of which fig. 50. is to be the primitive or horizon; the other, fig. 51., is to

serve for determining the position of the circles to be described on fig. 50. Draw the diameters N S, W E, N' S', W' E' in both circles perpendicular to one another; then N S in fig. 50. will be the projection of the meridian, and W E the projection of the circle passing through the east and west points of the horizon and the zenith, — that is, the prime vertical; N will be the north point of the horizon, S the south, and E and W the east and west points.

Make the arc N' P', or the angle N' C P', fig. 51., equal to the latitude of the place; join W' P' cutting C N' in P; make C P in fig. 50. equal to C P in fig. 51., and P, fig. 50., will be the projection of the north pole. Draw the diameter E Q, fig. 51., perpendicular to P' C p'; join W' Q meeting C S' in Q'. Take C Q, fig. 50., equal to C Q', fig. 51.; describe a circle through the points W, Q, E, and the arc W Q E will represent the equator. Next, to project the parallels of latitude, — for example, those which are 40° and 20° from the pole, — from P', fig. 51., take P' 40 and P' 40, each arcs of 40° on opposite sides of P'; also, P' 20, P' 20, arcs of 20° . Join W' 40, W' 40, meeting C N' in m and n; also W' 20, W' 20, meeting C N' in r and s. In N C S, fig. 50., take C m, C n, C r, C s, equal to C m, C n, C r, C s, fig. 51.; describe circles on m n, r s as diameters, and these will be projections of parallels of latitude at the distances of 40° and 20° from the pole. In this way may all the parallels, also the tropics and polar circle, be projected.

656. To project the meridians: in fig. 51. draw S' B perpendicular to N' S', meeting P' p' produced in B; take C A, fig. 50., equal to S' B, fig. 51., and through A draw a perpendicular to C A. Let us suppose that the meridians are to make with each other angles of 15° : at P, in the line P A, draw P 15 and P 15 on each side of P A, making angles with it of 15° ; and, in like manner, P 30, P 30, making angles of 30° , and so on to angles of 75° . On A, as a centre, describe a circle to pass through P; this will pass through W and E, and will be the projection of the six o'clock hour circle in the heavens, or that meridian on the globe that is perpendicular to the meridian of the place for which the projection is made. On the points 15, 15 describe arcs a P a', a P a' to pass through P, and meet the projection of the horizon in a, a'; a, a'; and in like manner on 30, 30 as centres describe the

arcs $b P b'$, $b P''$, &c. all passing through P: these will be the projections of meridians on the terrestrial sphere, or of hour circles on the celestial sphere. In this way, the projection may be completed.

3. GLOBULAR PROJECTION.

657. *In the orthographic projection, equal portions of the earth's spherical surface are represented by unequal plane surfaces; and the deviation from equality in the surface to be represented, and its plane representation, increases from the centre to the circumference of the projection.*

658. *The same is true of the stereographic projection, but with this difference, that the distortion in the representation of the figure of any portion of the spherical surfaces proceeds in a contrary direction: in the former case, the degrees of longitude and latitude are gradually contracted from the centre to the circumference; but in the latter, they are enlarged.*

659. In the stereographic projection, the projecting point, or point of view, is the pole of the circle on which the projection is made; and in the orthographic, it may be supposed in the axis, and at a very great, or rather indefinitely great, distance. It is this change of position of the point of view that produces the change in the direction in which the degrees of latitude or longitude are contracted. Hence it may be supposed, that, by taking a point of view at some finite distance greater than the radius of the sphere, a perspective representation will be obtained, in which the degrees in the representation will be nearly equal, and the deviation from equality in the representation of equal portions of the spherical surface in some measure corrected.

52

660. Let A D B (fig. 52.) be a section of the sphere by a plane passing through E, the point of view, and C the centre; draw the diameter F D to pass through E, and draw A C B perpendicular to D F. Since the whole quadrant A F is to be projected into the radius A C, if it be possible to make the representations of equal portions of it nearly equal, its halves A K and K F may be assumed as represented by A H and H C, halves of the radius: therefore, a line drawn from K to E must bisect the radius in H. This determines D E, the distance of the projecting point, to be equal to K G, a perpendicular from the middle of the quadrant.

B 661. To prove this geometrical proposition, draw AF and KC intersecting in I , and join HI . Then $AI = IF$ and $AI : IF :: AH : HC$; therefore HI is parallel to CF : hence, $KI : IC :: KH : HE :: GC : CE$. Now, $KI = FG$ and $IC = GC$; therefore $FG : GC :: GC : CE$: hence $FG \cdot CE = GC^2 = KG^2 = FG \cdot GD$; therefore $CE = GD$, and, taking away the line CD common to both, DE is equal to CG or to KG .

662. Hence it appears that the distance DE is the sine of 45° ; and therefore nearly 71 of such parts as the radius CA contains 100. This projection was first suggested by M. Delahire, and is now commonly called

the Globular Projection. If we suppose the quadrant A F divided into ten equal parts, then the projections of the arcs of 9° , reckoning from F to A, will be as in this table, in which the radius C A is supposed to be 10.

Arc.	Representation.	Arc.	Representation.
0° ... 9°	·991	45° ... 54°	1·017
9 ... 18	·994	54 ... 63	1·020
18 ... 27	·999	63 ... 72	1·015
27 ... 36	1·004	72 ... 81	·997
36 ... 45	1·013	81 ... 90	·950

From this table it appears, that the approximation to equality in the projection of equal arcs of a circle perpendicular to the plane of projection is considerable.

663. According to the principles of perspective, in this projection the circles of the sphere

will be represented by ellipses; and they have been so delineated in two hemispheres, projected, drawn, and beautifully engraved by Mr. Joseph Lowry, of London. He has placed London at the centre of the northern hemisphere, and instead of .707, Delahire's distance of the projecting point, he has made it .68 of the radius.

664. *In general, however, the projection is made on a meridian, and the circles of the sphere are represented by circles, and without any regard to the distance of a point of view. Also, the degrees of longitude on the equator, and of latitude on a meridian, are made all equal. With these simplifications, the meridians and parallels on a hemisphere of the earth's surface may be represented by the following construction:—*

665. *Let us suppose the parallels of latitude to be traced through every tenth degree, and that the meridians are to be an hour from each other.*

Describe a circle, E N Q S (*fig. 53.*), for the representation of the meridian. Draw the diameters E Q N S perpendicular to each other; one, E Q, to represent the equator, and the other, N S, the meridian, which is 90° from that on which the projection is made; N being the north, and S the south pole.

Divide the quadrants E N, Q N, and the radius C N, each into nine equal parts; let N 80, 80, 70, &c. be the equal divisions of the quadrants, and N c, c d, &c. the equal divisions of the radius: describe a circle through the three points 80, c, 80, and it will be the representation of the parallel of 80° of latitude; in like manner a circle described through the points 70, d, 70 will represent the parallel of 70° ; the remaining parallels, the tropics and polar circles, on both sides of E Q, the equator, are to be found in the same manner.

666. *Next for the meridians: divide the radii C E, C Q each into six equal parts at the points a, b, &c.; describe circles through the points N a S, N b S, &c. and these will be the representations of the meridians, any one of which, in laying down the positions of places by their latitude and longitude, may be assumed as the first meridian.*

II. CONSTRUCTION OF MAPS BY DEVELOPEMENT.

667. *The three methods of projection which have been explained are usually employed in the representation of a hemisphere, but are seldom used in delineating the geographical features of a single country. For these, the method of developement is commonly employed.*

668. *A perfect geographical representation of a country should represent all its parts in just proportion, and should exhibit its true figure. This is exactly done on the sphere; but it can only be nearly accomplished on a plane surface.*

669. *The purposes of civil government require maps that give the true figure and dimensions of territory. Military affairs require such as give correct distances; and navigation demands the exact bearing of one place from another. Ordinary maps fulfil approximately the two first purposes. The last is completely satisfied by a map of a peculiar construction, called Mercator's chart; but this is not immediately applicable to the other purposes.*

670. *It is a known property of a cone that its curve surface can be expanded into a plane: hence any figure delineated on it can always be exhibited exactly in all its dimensions on a plane surface. Now, a part of the surface of a sphere contained between two parallels of latitude, not very remote, will not differ much from the surface of a frustum of a cone that touches the sphere in the parallel midway between them; and this will also be true if it pass along the chord, or it pass partly within and partly without the sphere, cutting it between the middle and extreme parallels: in each case, the length of the slant side of the frustum must be supposed equal to the length of the meridian between the extreme parallels. On this principle, different constructions have been given for representing the surface of a sphere on a plane.*

1. Conical Developement.

671. *Let P A Q (*fig. 54.*) be a section of the meridian, P Q the axis, C the centre, E C the radius of the equator, B D any arc of the meridian, and A the middle point between B and D: draw the tangent A O, meeting the axis in O. Suppose now the plane figure O A E to revolve about the axis P Q; the semicircle P A Q will generate a sphere, and the tangent O A will generate the surface of a cone which touches the sphere in A. The points B, A, D will generate the parallels of latitude B b, A H a, D d, of which the middle parallel A H a will be a section of the cone perpendicular to its axis.*

672. Take H any point in the parallel $A H a$; draw $F H$ to its centre, and join $H O$.

54

Conceive now the cone to be expanded into a plane, and that the surface $O A H$ becomes, by developement, $O' A' H'$. The expansion of $A H$, the arc of the parallel of latitude on the sphere, whose radius is $F H$, the cosine of the latitude, will now become $A' H'$, an arc of a circle whose radius is $A' O' = A O$, the cotangent of the latitude of the parallel.

673. In $O' A'$ take $A' B'$ and $A' D'$, each equal to $A B$ or $A D$, and with the radii $O' B'$, $O' D'$ describe arcs $B' m$, $D' n$. The plane figure $B' m n D'$ may now be taken as nearly equal to the spherical surface bounded by meridians passing through A and H , and the portions of the parallels $B b$, $A a$ intercepted between them: and any tract of country delineated on the sphere may be

nearly shown by a delineation on the plane; the approximation being the more accurate as the breadth of the spherical zone is less.

674. Let the middle latitude $E A$ and the angle $A F H$, or breadth in longitude of the spherical surface, be supposed given, to determine the radius $O' A'$ and the angle $O' A' H'$. Because the middle latitude is known, its cotangent $O H$ is given in parts of the radius by the trigonometrical tables, or it may be expressed in minutes of latitude, by considering that half the circumference (to radius = 1) is 3.1416 ; therefore, the radius in minutes will be expressed by

$$\frac{60 \times 180}{3.1416} = 3437.7'.$$

Hence $O' A'$, the radius of the middle parallel in the developement, will be expressed in minutes of latitude by

$$3437.7' \times \cot. \text{ middle lat.}$$

675. Next, to find the angle $A' O' H'$. The arc $A H$ on the sphere and the arc $A' H'$ on the plane being equal; by the principles of geometry, the angle $A F H$ will be to the angle $A' O' H'$ as $A' O'$ to $A F$: now, $A' O' = A O$ is the cotangent of the middle latitude, and $A F$ is its cosine, and the cotangent is to the cosine as radius to the sine; therefore, putting L to denote the degrees of longitude between two meridians on the sphere, the angle $A' O' H'$, contained by the straight lines which represent them in the developement, will be in degrees

$$L \times \text{Sine middle lat.}$$

The angle O' , and the lines $O' A'$, $A' B'$, $A' D'$, in the developement, are now known; it remains only to divide $B' D'$, the representation of the arc of the meridian, and $B' m$, $D' n$, the parallels of latitude, into equal parts to form scales of latitude and longitude: then, circles described about O' as a centre, through the proper divisions of $B' D'$, will form the parallels of latitude; and straight lines drawn joining corresponding degrees on the extreme parallels $B' m$, $D' n$, will represent the meridians on the map; which is now ready for the delineation of the geographical features of the tract it is to represent. This is the way in which the common maps are constructed.

676. Example. Let it be required to construct a map to comprehend the British islands, which extend from 50° to about 61° of north latitude, and from 2° east to 9° west, about 13° of longitude. The middle latitude is $55^\circ 30'$, of which the cotangent in the tables is $.68728$ and sine = $.82413$. From these data, $O' A'$, the radius of the middle parallel, is $3437.7 \times .68728 = 2362.7$: the length of the arc $B D$ is $11^\circ = 660'$; therefore, $A' B' = A' D'$, its half, is 330 , and hence

$$O B = 2362.7 + 330 = 2692.7$$

$$O A = 2362.7 - 330 = 2032.7.$$

677. The number of degrees of longitude (L) in this case is 13° ; therefore (art. 675.) angle $A' O' H' = 13^\circ \times .82413 = 10^\circ 42'$.

Knowing now the radii $O' B'$, $O' D'$, and the angle O' , we can find the arcs $B' m$, $D' n$; or we can find their chords.

Thus we have,

$$\text{chord of arc } B'm = 2 OB \sin. \frac{1}{2}O' = 375'.6.$$

$$\text{chord of arc } D'n = 2 OD \sin. \frac{1}{2}O' = 502'.1.$$

We have now obtained the chords of 13° of longitude on the extreme parallels, and the meridians which form their extremities in minutes of a degree of the meridian; also the radii of the parallels of latitude: with these, the intelligent student of geography will find no difficulty in constructing a map of Britain.

2. Murdoch's Conical Developement.

678. *There have been various modifications of the conical developement*: of these, one was given by the Rev. Patrick Murdoch, in the Lond. Phil. Trans. 1758. Let M denote the arc of the meridian which is to be represented in a map: he proposed to make $O'A'$, the radius of the middle parallel, equal to

$$\frac{\text{chord of arc M}}{\text{arc M}} \times \text{Cot. mid. lat.}$$

the cotangent being supposed expressed by the radius of the sphere. The remainder of the construction is the same as the ordinary conical projection.

679. *By Murdoch's method*, the surface of the developement is exactly equal to the spherical surface which it represents, and the cone passes through points of the meridian between the middle latitudes and the extremities of the projected arc, its side being parallel to the tangent at the middle latitude.

3. De Lisle's Conical Developement.

680. *The astronomer De Lisle* employed the conical projection in constructing a general chart of the Russian empire, which extended from 40° to 70° of north latitude. He, however, supposed the cone to enter the sphere so as to cut it in two parallels midway between the mean and extreme parallels: these, in the developement, had the same dimensions as the corresponding circles of the sphere, and its whole extent differed but little from that of the tract it was meant to represent; because the excess at the two extremities of the chart was compensated, at least in part, by the opposite error in the middle.

4. Euler's Method.

681. *Euler was also occupied with this projection*: but he substituted for the determination of parallels which should be common with the sphere, that of the point of concurrence of straight lines which represent the meridians, and of the angle which they make when they contain one degree of longitude. His calculations rest on the following conditions:—1. That the errors are equal at the northern and southern extremities of the map. 2. That they are also equal to the greatest of those towards its middle. Hence he concluded that the point of concurrence of the meridians should be situated beyond the pole by a quantity equal to 5° of latitude, and that the angle of two consecutive meridians should be $48^\circ 44'$.

5. Flamsteed's Projection.

682. *The English astronomer Flamsteed*, in constructing his celestial atlas, developed all the parallels of latitude on the sphere into straight lines, and also one of the meridians; viz. that which passes through the middle of the chart: then the parallels, which are all perpendicular to that meridian, are exactly of the same length as on the globe, and consequently the degrees of longitude on the parallels will be shown in their just proportion, that is, as the cosines of the latitude. If, now, the parallels on the map be divided into equal parts, just as the parallels on the globe are, by the meridians, curve lines traced through corresponding points of division will represent the meridians.

683. *The adjoining figure (fig. 55.)* exhibits a sketch of a map of this construction.

684. *According to Flamsteed's method*, any distance on the map in the direction of the parallels is every where equal to the corresponding distance on the globe; but the configuration of places near the extremities is considerably distorted by the obliquity of the meridians to the parallels, so that the spherical quadrilaterals, the sides of which cross at right angles, are in the map represented by mixtilineal trapeziums, of which the angles are very unequal. Flamsteed employed this projection in representing the positions of the stars; but it is also employed in geography, particularly in delineating countries which extend on both sides of the equator: Africa, for instance.

6. *Modification of Flamsteed's Projection.*

685. There is a modification of Flamsteed's projection (fig. 56.), which has been extensively employed, and which deserves particular attention, because it corrects, in part, the defect of the obliquity of the meridians. This substitutes arcs of concentric circles for the straight line, which he proposed to represent the parallels of latitude. The common centre of the circles is in a straight line drawn through the middle of the map as an axis, and which represents a meridian; and its position in the axis ought to be such, that the obliquity of the angles made at the intersection of the curves which represent the meridians, and the circles which represent the parallels, should be as little as possible.

686. The position of the centre is so assumed, that the radius of the middle parallel of latitude is equal to its cotangent; and in this the modified projection of Flamsteed agrees with the ordinary conical projection.

687. To exemplify this construction, let it be proposed to describe the parallels and meridians for a map of Europe, which shall extend from 53° north latitude to 70° .

688. Let us, as in § 674, assume a minute of a degree of latitude for the unit of the scale from which the measures of the lines are to be taken. Therefore, as before, the radius of the sphere, of which a portion of the spherical surface is to be represented, will be 3437.7 minutes.

689. Let O A C B (fig. 56.) be assumed as the axis or middle meridian of the map; and let A D, B E be the halves of the part of the extreme parallels of latitude to be represented, and C the point in which the middle parallel ($52^\circ 30'$) cuts the axis; also, let O be the centre of the circles, arcs of which are to represent the parallels.

690. By the nature of the projection, O C must be taken equal to the cotangent of $52^\circ 30'$; this, to radius = 1, is .76733, and to a radius expressed by minutes, we have

$$O C = .76733 \times 3437.7 = 2637.8.$$

691. Having found O C, the radius of the middle parallel, the radius of any other parallel may be found by adding or subtracting its distance in minutes of the meridian from the middle parallel. Thus we find the radii of parallels differing by 5° , as in the following table: —

Parallel.	Radius.	Parallel.	Radius.
35°	3687.8	55°	2487.8
40	3387.8	60	2187.8
45	3087.8	65	1887.8
50	2787.8	70	1587.8

692. Next, we must find the points in which some one meridian cuts all the parallels. We shall suppose it to be 30° of longitude from O C, the axis of the map.

693. From the nature of the developement, the arc of longitude on any parallel in the map is equal to the arc of the parallel on the sphere which it represents. This has to an arc of the same number of degrees of the meridian the proportion of the cosine of the latitude of the parallel to the radius. Therefore, an arc of $30^\circ = 1800'$ on a parallel whose latitude is L will be in minutes,

$$1800 \times \cosine L.$$

694. By this formula, the lengths of the arcs may be easily computed by a table of logarithmic sines: but, for a practical construction, it will be more convenient to have the chords of the arcs. Now, in arcs not exceeding 30° , the arc diminished by a fraction whose numerator is the cube of the arc, and denominator 24 times the square of the radius, is very near equal to the chord; that is, a being put for any arc, and r its radius,

$$\text{chord } a = a - \frac{a^3}{24 r^2} \text{ nearly.}$$

695. From this formula, the chords may easily be deduced from the arcs.

696. As an example, let the arc of 30° of longitude, and its chord on the parallel 35° , be required. For facility of calculation, we shall use logarithms.

Calculation of Arc.				Calculation of Log. of $24r^2$.			
			Logarithms.				Logarithms.
$30^\circ = 1800'$	-	-	- 3.25527	Radius of arc 687.8	-	-	3.56677
Cosine 35°	-	-	- 9.91336				2
Arc $a = 1474'.5$	-	-	3.16863	Log. of square of radius	-	-	7.13354
			3	24	-	-	1.38021
From log. of cube of arc	-	-	9.50589	Logarithms $24r^2$	-	-	8.51375
Subtract Log. $24r^2$	-	-	8.51375				
Differ. of arc and chord $9'.8$	-	-	0.99214				

Thus, by an easy logarithmic calculation, we have found the arc to be $1474'.5$, and its excess above the chord to be $9'.8$. Therefore, the chord is $1464'.6$ of the meridian. By a like process, we have found the arcs of 30° of longitude, and their chords on the parallels to every fifth degree, as in this table.

Par. of Lat.	Arcs.	Chord of Arc.
35	1474.5	1464.7
40	1378.9	1369.4
45	1272.8	1263.8
50	1157.0	1148.7
55	1032.4	1025.0
60	900.0	893.6
65	760.7	755.5
70	615.6	611.8

697. Having now found the chord of 30° of longitude on the parallel of 35° to be $1464'.7$ of the meridian, we must, with compasses, place that distance taken from a scale of minutes from B to E, and to e ; and the points E, e will be in the representations of meridians 30° of longitude from the axis on each side. In the same way, the intersections of these meridians with the other parallels are found. Curve lines E D, cd must now be traced through all the intersections, and these will be the meridians in the map.

698. The intersections of the intermediate meridians with the parallels may be found by dividing each parallel into thirty equal parts, from the axis both ways; and as many meridian lines may be exhibited as may be thought necessary. In the figure here given they are traced to every tenth degree.

699. If the map is to extend further than 30° on each side of its middle meridian, the divisions of the parallels may be repeated on each, and meridians drawn.

700. This construction of a map is memorable, because it was adopted by the general *depôt* of war of France, about the year 1803, as the groundwork of a system of geographical charts which should exhibit the French original territory, as well as the additions which had been made, and were expected to be made, by conquest or negotiation.

Developement of the Curve Surface of a Cylinder.

701. The mariner, in navigating a ship between remote points on the globe, directs his course by the compass; steering as nearly as possible always in the same direction, supposing there are no obstacles to prevent him. If the place from which he sets out, and that of his destination, be due north and south from each other, the ship's path will evidently be a great circle, *viz.* the meridian passing through them. If, again, they have the same latitude, he must sail on a parallel of latitude; that is, his course must be due east or west. But if the places differ both in latitude and longitude, then it becomes a question, what is the nature of the line on the globe along which a ship must sail, with her head always in the same direction, as indicated by the compass, so as to pass from one to the other?

702. The line in question, which is called a *rhumb line* or *loxodromic line*, has manifestly this property, — it cuts all the meridians on the globe at the same angle. By this property, a ship sailing along it will move always in the same direction, as shown by a compass: but it will not be a great circle; for the equator is the only great circle that cuts all the meridians at the same angle; and hence it appears that the line on the globe by which a ship passes from one place to another is never the shortest possible, except when they are on the same meridian, or on the equator.

703. *Supposing a navigator had a perfect delineation of the earth on a sphere*, it is by no means evident how he should find the course he ought to steer to reach a remote port. By due consideration, however, he would see that the path must be a spiral. It would also be represented by a spiral curve on a map, formed by the developement of a cone; but navigators required charts before the theory of such curves was understood; therefore at that period his art must have been imperfect.

704. *The wants of the navigator*, accordingly, gave rise to the construction of a chart, in which the meridians and parallels were straight lines; and in this the developement of the curve surface of a cylinder was employed. Let us conceive that a zone of the earth's surface, of no great extent in latitude, is inscribed in or circumscribed about a right cylinder, whose axis coincides with that of the globe: the planes of the meridians will cut the curve surface of the cylinder in straight lines, parallel to the axis; and the planes of the parallels will cut it in sections perpendicular to the axis, which will be circles equal to the base of the cylinder. But in supposing the surface of the cylinder developed into a plane, these circles will become straight lines, perpendicular to the meridians. This developement has received the name of the *plane chart*: its invention is attributed to Henry, son of John king of Portugal. This kind of chart has nothing but its simplicity to recommend it; for the degrees of longitude have, indeed, their just proportion to the degrees of latitude in the parallel common to the cylinder and sphere, but in no other parallel.

705. *In the developement of a cylinder circumscribing the whole sphere*, the area of any zone in the sphere is exactly equal to that of its representation in the chart; and indeed the same equality may be observed in all cases, by a proper assumption of a parallel of latitude as the base of the cylinder. The developement, however, has this great fault, — the degrees of longitude always err in excess towards the north and in defect towards the south of the mean parallel, which is assumed as the base of the cylinder.

706. *There is a construction*, described in books of navigation under the name of a *plane chart*, the principle of which is somewhat different from that just described. In the seaman's plane chart the meridians are parallel straight lines, and so also are the parallels of latitude; and both are so laid down that a degree of latitude and a degree of longitude are equal in all latitudes. A chart of this kind, extending from 30° to 71° of north latitude, is given in *Robertson's Navigation*. It may easily be conceived how incompetent such a representation must be to the purposes of navigation or geography.

Mercator's Chart.

707. *The utter inadequacy of the old plane charts* to the wants of geography and navigation induced ingenious men to consider whether a chart might not be so constructed as to represent the meridians and parallels by straight lines, and at the same time readily show the true bearings of places from one another. The first that gave a true solution — at least an approximate one — of this important problem was GERARD MERCATOR, who was born at Ruremond, in Upper Guelderland, in the year 1512, and published a chart in 1556, wherein the rhumbs, which on the globe are spirals, were represented by straight lines, as in the plane chart; and so also were the meridians and parallels. It is not known by what principle Mercator constructed his chart; it has been supposed that he observed on a globe furnished with rhumbs what meridians the rhumbs passed in each degree of latitude: it is certain he did not know the true principles of the construction; for these were first found by Edward Wright, of Caius College, in Cambridge, who communicated his invention to his friend Thomas Blundeville, with a short table, showing the correct distances of the parallels of latitude from the equator, which was published in 1594 by Blundeville, among his *Exercises*. The truth of the divisions of Mercator's chart was then tried by the numbers given by Wright, and they were found to be inaccurate: hence it appears that Mercator did not understand the principles of the map bearing his name, and that this important invention is due to Wright, who explained it himself, in his treatise entitled *The Correction of certain Errors in Navigation*, published 1599, but written many years before.

708. *Although Wright's numbers were sufficiently correct* for all nautical purposes, and might be carried to any degree of accuracy, yet, in the progress of mathematical science, an improvement was made in his theory. Napier's invention of logarithms had proved an inestimable advantage to navigation and geography, by shortening calculations: this, however, was not the only advantage that the navigator derived from the invention; for, about the year 1645, Henry Bond showed that the division of the meridian in Wright's chart was altogether analogous to the logarithmic tangents of half the complements of the latitudes, and might be expressed by them. He seems to have found this by chance: such accidental discoveries are, however, never made but by men of genius. He could not demonstrate his important theorem. At last James Gregory proved its truth in his *Exercitationes Geometricæ*, published in 1668. The construction of the chart was now made perfect.

709. *The invention of Mercator's, or rather Wright's, chart*, one of the most important in the 16th century, affords a notable instance of the slowness with which men adopt improve-

ments in science. Although designed for the use of sailors, it was at first by no means generally used by them. William Burrough, a celebrated navigator, who had entered on his profession at the age of fifteen, and risen by his merit to the rank of controller of Queen Elizabeth's navy, objected to its usefulness. He said — "By Mercator's augmenting his degrees of latitude towards the poles, the same is more fit for such to behold as study in cosmography, by reading authors upon the land, than to be used in navigation at the sea." It is curious to observe that logarithms, the other grand auxiliary of navigation, met with a like reception from the German mathematicians that were somewhat advanced in years.

710. *Mercator's chart may be produced by developement*, as follows: — Conceive that a sphere, with the meridians and parallels and countries delineated on it, is enclosed in a hollow cylinder, and that the axis of the sphere coincides with that of the cylinder. Imagine now that the sphere is expanded in its dimensions, just as a soap bubble is produced by blowing air into it, or as a bladder would swell in all directions by inflation, the parts always stretching uniformly; the meridians will lengthen in the same proportion as the parallels, till every point of the expanding spherical surface comes into contact with the concave surface of the cylinder: the meridians will at last become straight lines, and the parallels, circles on that surface; the former in the direction of its length, and the latter parallel to its base, which is the equator. Suppose now the surface of the cylinder to be cut open along one of the meridians, and spread into a plane; the surface thus produced will be Mercator's chart.

711. *Mercator's chart is constructed, then, on the following geometrical principles:* — 1. The meridians are parallel straight lines at equal distances, for equal differences of longitude; and the parallels of latitude are also straight lines, perpendicular to the meridians. 2. Supposing a meridian on the globe be divided into minutes of a degree; one of these, at any parallel of latitude, will be to a minute of longitude taken on that parallel in the proportion of the radius of the equator to the radius of the parallel, which is the cosine of the latitude; that is, as the secant of the latitude to radius. Now the same holds true in the chart; that is, a minute of the meridian, at any parallel, has to a minute of longitude in that parallel the proportion of the secant of the latitude of the parallel to radius.

712. *By the first of these properties* a minute of longitude in the map is represented by a line of the same length in every parallel; therefore, by the second the minutes of the meridian will be represented by lines which go on increasing from the equator towards the poles. From this it follows that, if a minute on the equator be taken as the unit of a scale, and that unit be considered as the radius of a circle, then the representation of a minute of the meridian, at any latitude, will be expressed by the number in the trigonometrical tables which is the secant of that latitude. Thus it appears that, while the degrees of longitude on the equator form a scale of which the divisions are all equal in the map, the degrees of latitude marked on a meridian form a scale of which the divisions go on increasing from the equator towards both poles, each being the sum of the secants of all the minutes in the degree.

713. *The numbers which result from the addition of the secants of 1 minute, 2 minutes, and so on to the last minute of any arc of the meridian, reckoned from the equator, are given in books on navigation.* They form the table of *meridional parts*, and serve for laying down the position of any place in the chart. The addition of the secants is, however, only an approximation to the true length of the enlarged meridian in the chart; but it is sufficiently near the truth for nautical or geographical purposes. In strictness, also, it must be considered that the earth is not a sphere, but a spheroid, and on that account allowance ought to be made for its compression at the poles. The following short table shows the length of the enlarged meridian, both on the sphere and the spheroid, to every fifth degree of latitude. The compression is assumed to be $\frac{320}{321}$.

Lat.	Meridional Parts.		Lat.	Meridional Parts.	
	Sphere.	Spheroid.		Sphere.	Spheroid.
0°	0·00	0·00	50°	3474·47	3457·39

45	3029·94	3014·41			

714. To construct Mercator's chart (fig. 57.), draw two straight lines W E, N S at right

angles to each other, intersecting in C; of these W E is to represent the equator, and N S a meridian, in the middle of the chart: from any convenient scale lay off equal parts along the equator, from C both ways, to represent degrees of longitude, and each of which should, if there be room, contain 60 subdivisions for minutes.

715. Assuming the equator as a scale of minutes, lay off from C, north and south on the middle meridian, the number of minutes in the enlarged meridian, corresponding to each degree of latitude as shown by a table of meridional parts, of which that just given is an abridgment.

716. Draw straight lines through every fifth or every tenth degree of the equator and divided meridian, and perpendicular to them. The perpendiculars to the equator will be meridians, and the lines parallel to it parallels of latitude.

717. To put any place in its proper position on the chart, assume some one meridian for the first, and lay off from its intersection with the equator, and along it in the proper direction, the longitude of the place in minutes; draw a line through the point thus found perpendicular to the equator: this will be the meridian of the place.

718. On this meridian lay off the latitude, as shown by the table of meridional parts; and the point thus determined will be the true position of the place in the chart.

719. To find the bearing of one point from another, or course in which a ship ought to sail in passing from one to the other, draw a straight line joining the two points, and the angle which that line makes with the meridians is the course or bearing.

720. Thus, if L be the Lizard Point on the chart, and M the east end of the Island of Madeira, draw L I parallel to the meridian N S, and the angle I L M will be the course on which a ship ought to steer from the Lizard to reach Madeira.

721. The course may be found by a trigonometrical calculation, by considering that the meridional difference of latitude of the two places (as given by the table of meridional parts), and the difference of longitude in minutes, are the sides of a right-angled triangle, of which the line joining the places is the hypotenuse, and the course one of the acute angles, viz. that made by the meridian and line joining the places.

722. Again, the distance of the places, measured on the rhumb line passing through them, may also be found by trigonometry. It is the hypotenuse of a right-angled triangle, of which the proper difference of latitude (not the meridional difference) is one side, and the course the adjacent angle.

723. These properties of the chart apply alike to the bearings and distances of all places on the globe measured on rhumb lines. The bearing and distances of London, Edinburgh, and Dublin, for instance, from each, may be found in this way from a table of meridional parts and their known latitudes and longitudes.

724. It is evident that Mercator's chart does not serve well to show the figure of the countries on the globe, nor their relative magnitudes. These are purposes, however, which it is not intended to serve; but it does serve perfectly the purposes for which it was first constructed, and which, before its invention, were a desideratum in geography.

BOOK II.

GEOLOGICAL PRINCIPLES.

725. *Geology* is that branch of natural history which treats of the atmosphere, the waters of the globe, and of the mountain-rocks of which the earth is composed. No department of natural history abounds more in important facts and interesting conclusions; and therefore we shall lay before our readers a short view, 1st, Of the natural history of the atmosphere, or *meteorology*; 2dly, Of the natural history of the waters of the globe, or *hydrology*; and, 3dly, Of the solid materials of which the earth is composed, or *geognosy*.

CHAP. I.

METEOROLOGY.

726. *This beautiful department of science* makes us acquainted with all the properties and relations of the *atmosphere* which surrounds our planet. Although in general but little studied by geologists, a knowledge of it is, nevertheless, most useful in a geological point of view, of which the details we shall now lay before our readers will afford ample proof.

SECT. I. *Pressure, Height, Form, and Temperature of the Atmosphere.*

727. *The air* in which we breathe, with the clouds and vapours floating in it, surround the earth on all sides to an unknown height, and form a moveable envelope denominated the *atmosphere*. The human species, and other land animals, being thus entirely immersed in this fluid, may with some propriety be said to inhabit an ocean as really as the fishes which live in the great deep. But the latter have the advantage in being able to mount up, remain, or descend at pleasure in their element: whereas, without some additional aid, we must content ourselves with the more humble allotment of remaining on the bottom of our ocean. The winged tribes, doubtless, have the power of ascending to great heights; still they can never reach the summit. There is nothing more essential to the existence or health of man himself, or of the various inferior animals and vegetables which live on our globe, than the air or atmosphere; nor has any agent a greater share in the innumerable changes which are daily taking place on the inanimate materials composing our planet. It is not wonderful, then, that the composition and properties of the atmosphere should have so often excited enquiry. To give an account of these, and of their relations to other bodies, particularly to the various substances which are diffused in the atmosphere, and really or apparently deposited from it, constitutes the science of meteorology. Whilst engaging in this task, so far as our limits permit, it will be fully as instructive, and scarcely more tedious, occasionally to introduce a very brief sketch of the mode in which some of the leading facts were first discovered; but there is reason to think that a few of the more obvious properties of air have been known, as it were instinctively, from the remotest antiquity.

728. *That air is a body or substance* possessing the essential properties of matter, appears from the resistance which it offers to the occupation of its place by other bodies. Thus, if an apparently empty glass jar be first inverted, and then immersed in a vessel of water, that liquid will only enter a very little way into the jar, the rest being occupied by the air. This familiar experiment shows that air is a body, by its resisting the entry of the water. At the same time it shows the air to be an elastic or compressible substance, otherwise it should have completely excluded the water. That it is a fluid is evident from the ease with which bodies move in it, from its pressing equally in every direction, and passing with great facility through extremely minute openings.

729. *The ancients* must have been aware of these properties, or at least some of their practical applications, otherwise they could not have constructed their powerful air-guns, nor availed themselves of the principle of the diving-bell: for, in those early ages, the adventurers who dived in search of pearls, &c. were accustomed to hold large pots or kettles inverted on their heads. The air which these open vessels contained both excluded the water, and for a short time supported respiration; thus forming diving-bells in a portable shape. The ancients likewise, in some of their mechanical contrivances, availed themselves of that property of air by which it expands with heat and contracts with cold. It was on this principle that, in more modern times, Sanctorio constructed the air thermometer.

730. *Weight and pressure* are properties of the air as of all other bodies: it presses on the earth's surface, and on every other body with which it comes into contact. This was conjectured even by the ancients. But the effects which are now known to result from the weight and elasticity of the air were for a long time ascribed to a principle called *fuga vacui*, or nature's abhorrence of a vacuum.* So late as the beginning of the seventeenth century,

* Many principles laid down by our philosophers have been found false or imperfect; but they were truly the general expression of the phenomena then known. Aristotle saw, for example, solid or fluid bodies fall towards the ground when they ceased to be supported, gaseous bodies rise from the bottom towards the surface of the water, and flame direct itself towards the sky; and he concluded that air and fire had a tendency

it was generally believed, that the ascent of water in pumps was owing to this principle, and that by means of suction fluids might be raised to any height whatever. But Galileo, though still inclining to the old opinion, remarked that water did not rise in a common pump unless the sucker or bucket reached within 34 feet of its surface in the well. Hence he was forced to conjecture, that not the power of suction, but the pressure of the atmosphere on the surface of the well, was the cause of the water's ascent; that a column of water 34 feet high was a counterpoise to one of air on an equal base, but reaching to the top of the atmosphere; and that, for this reason, water could not follow the sucker any farther.

731. *Torricelli*, a disciple of Galileo, profited by this hint. It occurred to him that the same force which supported water to the height of 34 feet would sustain a column of any other fluid which weighed as much on an equal base; and therefore mercury, being 13.6 times as heavy as water, should only be suspended to the height of 29 or 30 inches. Accordingly, he took a glass tube from three to four feet long, and closed at one end; this he filled with mercury; then, stopping its mouth with his finger, he inverted the tube, and on re-opening its mouth in a vessel of quicksilver the result verified his expectation. The mercury, obeying the laws of hydrostatics, descended in the tube till the vertical column was about 30 inches above the level of the cistern, leaving the remaining space at the top empty or nearly a vacuum. Hence he inferred that it was only the weight or pressure of the atmosphere on the mercury in the cistern which balanced the column in the tube. This is usually called the *Torricellian experiment*, and is the foundation of the barometer.

732. *The mean pressure* is every where the same at the level of the sea, and equal to about $14\frac{1}{2}$ lbs. on the square inch. It becomes less as the place is elevated above the sea, and greater if below its level. The pressure of the atmosphere, as measured by the mercurial column, varies somewhat at every place on the earth's surface. Generally speaking, its variations are greatest in the temperate zones, decreasing towards the equator and poles. The annual range rarely exceeds half an inch in the torrid zone. It is about two inches at London, and the same at St. Petersburg, but rather less at Melville Island. It nowhere exceeds $3\frac{1}{2}$ inches. The annual range is more considerable at the level of the sea than on mountains; and under the same latitude it is less, as the height of the place above the sea is greater. The barometer has a tendency to rise from 4 P.M. to 10 P.M.; to fall from 10 P.M. to 4 A.M.; to rise from 4 A.M. to 10 A.M.; and again to fall from 10 A.M. to 4 P.M. Different authors, however, differ a little both as to the hours and the amount of the diurnal variation, which appears to be greater as the latitude is lower. The barometer is likewise elevated a little at the quarters of the moon, and depressed at the new and full. The range of this instrument is greater in winter than in summer.

733. *The barometer ranges* higher in proportion as the weather is more serene and settled; calm weather, with a tendency to rain, depresses it; high winds have a similar effect, especially from the west and south, during which it sometimes sinks very low without rain. On the other hand, the barometer generally rises with northerly and easterly winds, even though accompanied with rain. In extra-tropical climates, a fall in the barometer, without a change or rise of wind, is usually followed by rain.

734. *The law which regulates the elasticity of the air* formed the next important step, after the discovery of the pressure. It was made by Boyle in England, and Mariotte in France, who discovered, much about the same time, that the temperature being the same, the pressure or elastic force of air is directly as its density, or inversely as the space it occupies. This law, though received as correct at the time of its discovery, came to be frequently called in question during more than a century after. In making experiments on this subject, there are many sources of error to be guarded against; and it would have been nothing remarkable though the first conclusions had been a little inaccurate. Indeed the law continued to be suspected till within these few years. But MM. Dulong and Petit have more recently examined it through a wide range of temperature, Professor Oersted has tried it under a great variety of pressures; and within the limits of their experiments the law was found to hold good. The writers of certain popular works just publishing do not seem aware of this, as they still state the old doubts in all their force.

735. *The variable capacity for heat* forms another property of air of no less importance, but which seems to have been little known or attended to till towards the end of the last century. When air undergoes a change of volume, it at the same time changes its capacity for

to ascend, earth and water to descend. We now know that these motions, although inverse, are the result of a single power; but we have arrived at this discovery after the insufficiency of the first explanations were rendered manifest by new facts. The same remark applies to the much vituperated principle of the *horror of a vacuum*. Aristotle did not establish it *à priori*, he only announced it as the general expression of the facts then known. If he had seen water stopping in pumps at a height of thirty-two feet, and mercury rising to twenty-eight inches in the Torricellian tube, perhaps on comparing the specific weights, and the height of the two columns, he would have been led to discover the true cause of the phenomenon. We may remark, that so long as experiment had not shown the contrary, it was just as rational to suppose that bodies had a disposition to carry themselves wherever a vacuum tended to form, as to admit that they attract each other, as is now believed. The principle of the *horror of a vacuum* is found false; but it has nothing absurd in itself, and can only seem so to persons who take in the literal sense a figurative expression, (an expression perfectly similar to many others which we employ without scruple,) because language does not furnish us with any that are perfectly rigorous.

heat: becoming hotter by compression, and colder by rarefaction. The want of acquaintance with this circumstance led Newton, and many others after him, into the mistake of concluding, that the particles of elastic fluids repel each other with forces inversely as their central distances; which cannot be the case if the capacity be affected, no matter in what manner or degree, by a change of density. But very extensive experiments, made by some of the most eminent scientific men in France, and repeated in this country, are favourable to the idea that the particles of air observe the same law as magnetism and electricity, repelling each other with forces inversely as the *squares* of their distances.

736. *There is a gradation of density in the air.* Being, as already stated, a compressible body, it is obvious that the lower parts of the atmosphere, by sustaining the greater weight or pressure of the air above them, must be so much the more condensed; and therefore, as we ascend in the atmosphere, the density will continually diminish. Accordingly, it may be shown from the principles already laid down, that were the temperature and the force of gravity uniform at all heights above the earth's surface, the densities of the strata would decrease in geometrical progression for altitudes taken in arithmetical progression, so as nearly to halve the density for every 3.5 miles of ascent. But, independently of a trifling change in the force of gravity, this is not exactly the law of nature; for it is found that the temperature generally decreases as we go upward, and that not according to any fixed law. Hence the relation between the density and altitude is not of a steady character, and can only be obtained in any particular case from observing the pressure, temperature, and hygrometric state of the air. This is a research to which many eminent men have turned their attention; and their successive labours have led to the formation of convenient rules, by which the heights of mountains can be obtained to a considerable degree of accuracy, and with great facility, by means of the barometer, &c.

737. *The height and form of the atmosphere are objects of interest.* With an uniform temperature, the law of Boyle would involve the notion that its height is infinite; but this is an idea which has scarcely any supporters, and is generally believed to be incompatible with the laws of motion. Dr. Wollaston, whose opinion is entitled to great deference, maintains that the atmosphere must terminate at the height where the repulsive force between its particles equals their tendency to gravitate towards the earth. The law of gravity may be admitted as known, but the same can hardly be affirmed of the law which regulates the repulsive force, so long as the temperature at great heights is unknown; and this circumstance leaves the boundary undetermined. A doubt of a more serious nature, however, attaches to this speculation, on the ground that we are totally ignorant with what materials the air may be mixed at great elevations. The atmosphere is generally supposed to be higher at the equator than at the poles; but we have neither data for computing the heights, nor the proportion in which they differ: so that the oblate spheroidal figure which some give to the atmosphere can be considered as little else than an ingenious conjecture.

738. *The temperature of the atmosphere has great influence on most meteorological phenomena; but it is exceedingly variable, and can as yet be determined only by actual observation on the spot.* Nothing would tend to throw greater light on many of the unresolved questions in meteorology, than a ready mode of computing with certainty the temperature which obtains at any instant in a point of the atmosphere remote from the contact of the earth's surface, and at any point on the surface remote from the observer: but these are likely to continue desiderata. The very little that is known of the temperature of air remote from the earth's surface has been derived from a few æronautic excursions, particularly the unexampled ascent of M. Gay-Lussac to the height of 7630 yards.

739. *Mr. Dalton, about the commencement of the present century, proposed a theory of gradation of heat in the atmosphere, on the supposition that the same weight of air, taken anywhere in a vertical column, contains the same quantity of heat; and hence he concluded that the temperature ought to be regulated solely by the capacity of the air for heat at the particular density.* This theory seemed very plausible at the time, was embraced by some of the first sages of the age, and appeared to agree sufficiently with what was then supposed to be known of the variable capacity of air for heat. But simpler and more accurate experiments have since shown, that the decrease of temperature due to rarefaction far exceeds that observed in æronautic ascents; and therefore, if such observations are to be depended on, there must be other causes which interfere with Dalton's law.

740. *The heat of the air in one shape or other is no doubt greatly derived from the sun, either immediately, by intercepting the solar rays, or indirectly, from its contact with the earth's surface, which is more or less heated according as it is turned more or less towards the sun: but whether heat, in return, be projected from the earth or its atmosphere towards other regions of space, is a disputed question.* Professor Leslie maintains that heat, which is not accompanied with or rather in the state of light, cannot pass through a vacuum, and, of course, that it cannot pass the boundary of the atmosphere. If so, it would follow that the atmosphere does not continually draw off heat from the earth, but may oftener be the warmer of the two. Many philosophers, however, are of a different opinion, among whom was the late ingenious Dr. Wells, with most of those who embraced his theory of dew. These allege,

that heat is constantly projected from the earth and atmosphere towards the boundless regions of space. Observation shows, that much heat passes upward from the earth's surface, especially when the air is clear. In this way, the stratum of air in contact with the surface is cooled more than that which is somewhat higher. It is probable that there exists a natural tendency in the atmosphere, as in most other bodies, towards an uniform temperature throughout its whole height; and since currents in its upper regions usually come from a warmer quarter, and the lower currents from a colder, there is upon the whole, independently of aëronautic observations, some ground for supposing that the decrease of temperature on ascending in the atmosphere should be slower than the law of capacity as increased by dilatation requires.

741. *The following list of temperatures, chiefly observed at stations employed in the barometrical measurements of heights, is taken from M. Ramond's work on that subject. Only a few of these measurements embrace the whole heights of the mountains on which they were made, and the first case is of a different class. We have reduced the temperatures to Fahrenheit's scale:—*

Places.	Height.	Temp. at bot.	Temp. at top.	Places.	Height	Temp. at bot.	Temp. at top.
	Yards.	°	°		Yards.	°	°

Mont Perdu, Barèges	2354	77.0	44.4				

This table shows, in a very striking manner, with how little certainty the decrease of temperature can be estimated from the increase of height; and how unsteady the rate of decrease is often at the same place. M. Ramond, however, has collected some cases which are still more discordant.

742. *Professor Leslie has given a very simple formula for determining the difference between the temperatures at two stations, by means of the barometer: it gives nearly the mean of the results in the foregoing table, or about 1° for every 100 yards of ascent, and may therefore be of some use in the present imperfect state of this branch of science. Let B be the height of the barometer at the upper station, and β that at the lower: then the Professor's formula for the difference of temperature, by Fahrenheit's scale, is $45^{\circ} \left(\frac{B}{\beta} - \frac{\beta}{B} \right)$; and by the centigrade scale, $25^{\circ} \left(\frac{B}{\beta} - \frac{\beta}{B} \right)$.*

743. *Experiments made on the change of temperature in air, due to a given change of pressure, give a somewhat wider range of temperature than that observed in the atmosphere. Let t be the temperature on Fahrenheit's scale at the lower station: then, if the decrease of temperature were regulated solely by the density, it would be $(448^{\circ} + t) \left[\left(\frac{B}{\beta} \right)^{\frac{1}{4}} - 1 \right]$.*

744. *The preceding table contains the temperatures of the air at different heights for one or a few particular instants; but we shall now add a table from Baron Humboldt of the mean temperatures of elevated situations, as deduced from several years' observations. The degrees are those of Fahrenheit's scale.*

745. *From this table it appears, that, in the mean state of the atmosphere, the temperature does*

Height in English feet.	Equatorial zone from lat. 0° to 10°.		Temperate zone from lat. 45° to 47°.	
	Mean Temp.	Difference.	Mean Temp.	Difference.
0	81.5	0	53.6	0
3195	71.2	10.3	41.0	12.6
6393	65.1	6.1	31.6	9.4
9587	57.7	7.4	23.4	8.2
12792	44.6	13.1		
15965	34.7	9.9		

not decrease uniformly for a uniform ascent. At the equator, the thermometer falls 10° in the first 1000 yards of ascent, or about 1° for 310 feet. In the next 1000 yards, it is only 1° for 524 feet; but in the third and fourth stages there is a remarkable acceleration, which, having attained its maximum rate, is diminished again in the fifth stage to somewhat less than it was in the first, or to 1° in 320 feet. The mean rate in the variation of temperature, throughout the whole height of 15965 feet, at the limit of perpetual snow, is 1° for every 341 feet. The smaller rate of decrease in the second and third stages is ascribed by Humboldt to the large dense clouds which are suspended in this region, and which, he alleges, have the triple effect of absorbing the sun's rays, forming rain, and intercepting the radiation of heat from the

earth. In the temperate zone, the decrease is at the rate of 1° for 253 feet, during the first 1000 yards of ascent. But throughout the whole height of 9587 feet, to the limit of perpetual snow, where the mean temperature is 23.4° , the decrease is 1° for 317 feet, or almost 1° for 100 yards. As already remarked, observations made in the free regions of the atmosphere have not yet been so numerous as to warrant any certain conclusion regarding the temperature; but, so far as such observations go, they do not differ very widely from the mean of those observed on the sides and summits of mountains. But generally in the temperate zone, a difference of 1000 yards in height will produce a difference of 12° of temperature; and so on in proportion for smaller heights. In higher regions, the difference between the heats of day and night, summer and winter, seem to be less than at the level of the sea; though from this there are some exceptions. Extensive table-lands are usually warmer than insulated peaks of the same height. Humboldt calculates that, in the temperate zone, an ascent of 110 yards diminishes the temperature as much as an additional degree of latitude.

746. *Temperature of air in mines.* Having thus noticed the lower temperatures which obtain in more elevated situations, we shall now give some account of the increased temperature which generally prevails in air occupying deep caverns and mines. There can be no doubt as to such facts, but the source of the heat is still a subject of controversy. There are some mines intensely cold; and as these were first observed, the explanation offered was, that the colder portions of air had, by their greater weight, descended into the mines: but this solution entirely vanished when it was known that mines are generally hot. The heat of the workmen, their fires and lights, have been stated as sources of heat; as likewise the chemical action of air and water on the minerals. Some again allege that a high temperature obtains in the interior of our globe, and consequently that the heat will always be greater as we penetrate farther. However, it is found that on boring into the solid strata in the bottom of warm mines, and letting down a thermometer, the temperature, so far from increasing, comes short of that in the mine. This sufficiently proves that, whatever be the sources of heat, some of them at least must operate in or be situated about the mine itself. That a high temperature obtains in the interior, is in many instances evident from the streams of hot water and vapour which issue from fissures in the strata: but in many warm mines nothing of this is observable. Professor Leslie, Dr. Forbes, and afterwards Mr. Matthew Miller, have suggested the heat evolved by a current of air, while it undergoes an increase of pressure in descending into the mine. The first two of these philosophers did not deem this an adequate source of heat; and Mr. Miller seems to entertain similar doubts. But from what is now known of the great heat evolved by the compression of air, there can be little room to question that this furnishes a considerable supply, wherever there is a sufficient current of air. Thus, if air at the temperature of 62° F. have its density suddenly increased by the 170th part, the temperature will be raised 1° ; supposing no heat to be lost on the sides of the shaft. This would give 1° for a descent of 170 feet, which is still short of the rate at which the temperature is observed to increase in British mines; but when added to the heat caused by the presence of the workmen and horses, their lights, blasting of rocks, fires, &c. together with some increase of temperature belonging to the deeper strata, there does not seem any mystery in the heat of some, although probably not of all, mines. Those mines, again, in which there is almost no circulation of air, and which present a wide mouth to a clear sky, may have their temperature reduced by radiating heat upwards, in the same way that plants are starved with cold by being too much sheltered from the wind while they are exposed to a clear sky.

747. *An immense collection of facts and observations relating to this subject may be seen in the Transactions of the Geological Society of Cornwall, and in the first Number of the Edin. Phil. Journal.* From the latter we extract the following summary of Mr. Bald's observations, made in the deepest coal-mines in Great Britain:—

<i>Whitehaven Colliery, County of Cumberland.</i>		Water at depth of 444 feet	- - - -	61° F.

748. *The temperature of springs and caverns*, in many places, coincides with the mean annual temperature of the air: but Humboldt alleges that, in latitudes above 45° , the mean heat of springs and caves exceeds that of the atmosphere. As connected with this subject, Mr. Ferguson, of Raith, had four large thermometers sunk in his garden, to the respective depths of 1, 2, 4, and 8 feet, in lat. $56^{\circ} 10'$, and 50 feet above the sea. The stems and scales rose above ground, and indicated the following monthly mean temperatures:

	1816.				1817.			
	1 Foot.	2 Feet.	4 Feet.	8 Feet.	1 Foot.	2 Feet.	4 Feet.	8 Feet.
January - - -	33.0°	36.3°	40.7°	43.0°	35.6°	38.7°	40.5°	45.1°

Mean of the Year	43.8	44.1	45.1	46.0	44.9	45.9	46.2	46.6

Had the thermometers been sunk considerably deeper, they might have been expected to have indicated $47^{\circ} 7'$, which is the constant temperature of a neighbouring spring issuing from a trap rock.

749. *The local temperature or climate* of a country depends very much upon its distance from the equator, and its height above the level of the sea: but the nature of the surface, the proportion of humidity, the distance of the sea, of lakes, of mountains, of arid or frozen plains, and perhaps, also, the internal heat of the earth, have each their share in the fertility or salubrity of a country. The decrease of heat as we recede from the equator follows dif-

Lat.	Old World.	New World.	Diff.
0°	81.5°	81.5°	0°
20	77.9	77.9	0
30	70.7	67.1	3.6
40	63.5	54.5	9.0
50	50.9	38.3	12.6
60	41.0	25.0	16.0
70	33.0	0.0	33.0

ferent laws in the two hemispheres, being greater in the southern than in the northern, and is also affected by the longitude. On the west of Europe, the cold increases less with the latitude than in any other quarter. Under meridians which are 90° either east or west of London, the increase of cold, as we go northward, is more rapid than in England. According to Humboldt, continents and large islands are warmer on their western sides than on the eastern.

The annexed table shows the mean temperatures of western

Europe and North America continued to the equator.

750. *Isothermal lines* have been considered as measuring the heat and cold of the earth. The climate of Eastern Asia comes nearer to that of Eastern America than of Western Europe. Thus the latitudes of Naples, Pekin, and Philadelphia are respectively 41° , 40° , and 40° , whilst their mean temperatures are 63.3° , 54.8° , and 53.4° . Such differences are rendered more sensible when we connect the places having the same mean temperature by lines which Humboldt denominates *isothermal* lines. Thus, the isothermal line of 59° F. traverses the latitude of 43° in Europe, but descends to lat. 36° in America; the isothermal line of 41° F. passes from lat. 60° in Europe to lat. 48° in America: but since the western coast of North America is warmer than the eastern, the isothermal lines, being traced round the northern hemisphere, would have concave summits at the east side of both worlds, and convex at the west.

751. *The difference between the mean temperature of summer and winter* is nothing at the equator, and increases continually with the latitude. But the extreme difference of the seasons is comparatively small in Western Europe, and great where the mean annual temperature is low, as on the east coasts of Asia and America. If we draw a line in a north-east direction from Bourdeaux to Warsaw, and continue it to the Wolga, in lat. 55° , then all places under this line, at the same elevation, will have nearly the same summer temperature of 69° or 70° F. The lines of equal winter temperature decline in an opposite direction. Thus a straight line drawn from Edinburgh to Milan, almost at right angles to the former line, would pass over places which, if equally elevated, would have nearly the same winter temperature of 37° or 38° F.

752. *The extremes of temperature* are experienced chiefly in large inland tracks, and little felt in small islands remote from continents. In the United States intense cold is felt when the wind blows from the frozen regions round Hudson's Bay. From snow-clad mountains, gusts of cold wind, called *snow winds*, rush down and cool the adjacent plains. The heat accumulates to an astonishing degree when the wind passes over extensive deserts of burning

sand, which are said, in some instances in Africa, to be heated to the boiling point. This fine sand, or rather dust, sometimes rises in the air and obscures it like a fog, communicating to it an intolerable heat. In arctic countries the temperature is very much regulated by the freezing of the water and the melting of the ice; by the freezing of the water great quantities of heat are given out which moderate the severity of the winter's cold, and thus save from destruction the arctic land, animals, and plants; while in summer, the intensity of the heat, produced by the long continuance of the sun above the horizon, is moderated by the abstraction of a considerable portion of that heat by the water during the melting of the ice. Had the arctic regions been entirely of land, neither plants nor animals could have existed in them: for during summer, owing to the sun remaining above the horizon for months, an elevation of atmospheric temperature would have been produced fatal to animals and plants; and in winter, the long darkness and intense cold would have proved equally fatal to animated beings. The cold of the icy regions of the north has been alleged to reach, by currents of air, southern latitudes, and thus to lower their temperature.

753. *Baron Humboldt has added more to our knowledge of the distribution of temperature over the globe than any other who had laboured in the same boundless field of research. The following is his general summary, to which we have added Melville Island. The temperatures have been reduced to Fahrenheit's scale, and the longitudes are reckoned from Greenwich. An asterisk is prefixed to those places whose temperatures have been most accurately determined, and in general by means of 8000 observations.*

754. *In treating on the mean annual temperature which obtains at different places, it is customary to give a table which makes the temperature depend entirely on the latitude.* But observation shows, that the temperature is usually higher at the same latitude in the old world than in the new, and in north latitude than in south; and, as was already mentioned, it differs in the same continent under different meridians. So that more than one table would be required for each quarter of the globe; or else one very extensive table, involving the longitude as well as latitude, which is the case with Humboldt's table, so far as it goes.

755. *As the earth and its atmosphere are continually receiving heat from the sun, it is plain that their mean annual temperature must be continually on the increase, if no heat be thrown off by them into surrounding space.* Professor Leslie accordingly alleges, that the increase of temperature is at the rate of about 1° in 80 years. This would help to explain some of the changes of climate which seem to have been gradually taking place during successive ages in many places, and particularly in the west of Europe. But the late celebrated Marquis de la Place has endeavoured to show, from astronomical observations, that the mean temperature of the earth has undergone no sensible change during the last two thousand years. His arguments, however, are not free from objection.

SECT. II. *Effect of Climate on Plants and Animals.*

756. *The geographical distribution of plants and animals appears to be chiefly regulated by the temperature of the atmosphere.* Each has generally a particular climate in which it thrives best, and beyond certain limits it ceases to exist. Since an increase of height has an effect on climate in some respects similar to an increase of latitude, it has been commonly supposed that there are properly no plants peculiar to high latitudes, because such may be raised on the mountains under the equator, which embrace every variety of climate between their summit and base, at least in so far as temperature is concerned. In point of atmospheric pressure, however, the two situations differ essentially; and some naturalists allege, that pressure is of vital importance to the growth of plants. Professor Dobereiner is of opinion that the diminutive size of plants, in elevated situations, depends more on the diminution of pressure than of temperature. To ascertain this, he put equal quantities of barley and moist earth into two equal receivers: the air in the one had a pressure of 14 inches of mercury, and the other 56; germination commenced in both at the same time, and the leaves had the same green tint. At the end of fifteen days, the shoots in the rarefied air were 6 inches long, and in the other from 9 to 10. The first were expanded and soft and wet on the surface, especially towards their extremities; the others were firm, rolled round the stem, and nearly dry. In some respects, this accords with what Humboldt observed of the trees on the Andes, that water transpires from them even in the driest weather. But such experiments are inconclusive, unless there were some contrivance employed to renew the confined air frequently. Independently of pressure, the barley in the condensed air had the use of four times the quantity of air in the other vessel.

757. *Plants are most numerous, and exhibit the greatest variety of species, and the most luxuriant growth, within the tropics, beyond which they gradually diminish.* In the arctic regions, and in the north of Russia, the vegetable kingdom has dwindled to almost nothing. The lines which limit the growth of certain plants depend on the average summer temperature, for plants which require a long and moderate heat; on the temperature of the warmest month, for those which require a short but great heat; and on the temperature of the coldest month, for those which cannot bear cold. The transparency of the air is also of importance to many plants; but our limits will not admit of enlarging, and therefore we shall confine ourselves to a short account of the climates of cultivated plants. The plantain, which is a primary article of food in tropical America, requires a temperature from 82° to 73° F., which occurs between lat. 0° and 27° : but, in the equinoctial zone (lat. 0° to 10°), its fruit does not ripen at a greater altitude than 3300 feet. The sugar-cane has nearly the same range, but is cultivated, though with less advantage, in the old world to lat. $36^{\circ} 5'$, where the mean temperature is about 67° . The severity of the North American winter prevents the cultivation of the sugar-cane beyond lat. 31° ; but it succeeds at an altitude of 5700 feet on the table land of Mexico. The favourite climate of the cotton plant lies between lat. 0° and 34° ; but it succeeds with a mean summer heat of 75° or 73° F., if that of winter do not descend below 36° or 38° . In America, it is cultivated at lat. 37° ; in Europe, lat. 40° ; and in Astracan at lat. 46° . The date palm thrives best between lat. 29° and 35° ; but, when sheltered from the north wind, it is cultivated on the shores of Italy to lat. 44° . The citron has nearly the same range, but is cultivated at Nice, at altitudes of 400 feet. This tree, with the sweet orange, grows in Louisiana to lat. 30° , but beyond that it is injured by the cold. The olive ranges in Europe between lat. 36° and $44^{\circ} 5'$; it succeeds wherever, with a mean annual temperature from 66° to 58° F., that of summer is not below 71° , nor that of the coldest month below 42° , which excludes all North America beyond lat. 34° . The favourite climate of the vine in the old world is between lat. 36° and 48° ; but it thrives wherever the mean temperature is from 62° to 47.5° , provided that of winter is not below 33° , nor summer under 66° or 68° . Such is the case on the shores of Europe

to lat. 47° , and in the interior to lat. 50° , but only to lat. 40° in North America. The *cerealia* or common grain, as wheat, rye, barley, and oats, thrive where the mean annual temperature descends to 28° F., provided that of summer rise to 52° or 53° . In Lapland, barley ripens wherever the mean temperature of summer rises to 47° or 48° . The rapid growth of barley and oats adapts them to the short summers of the north: they are found as high as lat. $69\frac{1}{2}^{\circ}$ in Lapland, along with the potato. In some parts of eastern Russia, no grain is found beyond lat. 60° . Wheat, which is a precarious crop, and little cultivated beyond lat. 58° in western Europe, yields good returns in this part of the temperate zone, when the mean heat, while the grain is on the ground, is 55° ; but if no more than 46° , none of the *cerealia* come to maturity. These species of grain are cultivated at a height of 3500 feet on the Alps, in lat. 46° . Barley and oats succeed at double that height on Caucasus, and at almost a triple height on the Andes, along with wheat and rye. In the west of Europe, maize has the same range as the vine, but reaches farther north on the east. In its native American soil, it forms the chief article of food, from the river Plata to the lakes of Canada. Requiring a short but warm season of four months, it is well suited to the climate of the New World up to the latitude of 45° . The oak ceases at lat. 63° in Norway, at 60° or 61° in Finland, and at 57° in the government of Perm. The *pinus silvestris*, or Scots fir, grows to a height of 60 feet in Lapland, at lat. 70° , and 850 feet above the level of the sea: there the birch is found at double that elevation. In eastern Russia, the larch, pine, birch, and mountain-ash, disappear about lat. 68° ; and, at Hudson's Bay, all trees cease about lat. 60° .

SECT. III. *Composition of the Atmosphere. Aqueous Meteors.*

758. *Regarding the composition of the atmosphere*, abundantly vague and fanciful notions prevailed for many ages. The ancients considered air as one of the four simple elements, of which they supposed all other bodies to be compounded. These were earth, air, fire, and water. How far the opinion was correct, which made fire an element, is a question on which nothing is yet known; but the researches of modern chemistry have shown that the other three are all compound bodies. The chief, and perhaps the only essential, component substances in the atmosphere, are the two gases called oxygen and azote; its other ingredients, occurring only in small and variable quantities, are rather to be considered as foreign bodies. The analysis of air is a difficult problem. Many chemists have found it to consist of 21 parts by volume of oxygen to 79 of azote; and this proportion is sensibly the same whether the air be from the polar or tropical regions, from the level of the sea or a mountain top, from the most healthy or insalubrious countries. But Dr. Prout, guided by the laws of definite proportions, alleges, that if the two gases of which air principally consists be really combined, they ought to be 20 oxygen to 80 azote; and it must be allowed that similar conjectures of the same eminent chemist have been verified regarding the composition of other bodies, which had apparently deviated farther from the atomic system.

759. *The investigation of the component parts of the atmosphere* did not keep pace with that of its mechanical properties. Boyle, however, and his contemporaries, put it beyond doubt that it contained an elastic fluid and water in the state of vapour. They also conjectured that it contained various other substances, which rose from the earth in the form of vapours, and often altered its properties, rendering it noxious or fatal. Since the discovery of carbonic acid by Dr. Black, it has been ascertained that this elastic fluid always constitutes a part, though a very minute one, of the atmosphere.

760. *With respect to moisture*, or the state in which water exists in air, two opinions have been formed: 1. Water may be dissolved in air, in the same manner as salt is held in solution by water; 2. It may be mixed with air in the state of steam or vapour, after having been converted into vapour. The first of these was hinted at by Dr. Hooke, and afterwards proposed by Dr. Halley. It has been adopted by many others in succession, among whom is Professor Leslie; and it cannot be denied that many of the phenomena agree with that theory. The second opinion seems to have originated with Mr. Deluc; but it is to Mr. Dalton and M. Gay Lussac that we are indebted for subjecting this theory to the test of experiment.

761. *Evaporation* from the waters on the surface of the earth is undoubtedly the source whence the moisture which exists in air is derived. Accordingly we find that water exposed to the air suffers a gradual diminution of bulk, till it entirely disappears. It is then said, in common language, to have dried up, or to have *evaporated*. Under an exhausted receiver, water diminishes even more rapidly than in the open air. Were this owing to solution, the very reverse ought to follow; because, in place of vapour being caused by the presence of air, it goes on more rapidly in its absence. By comparing a set of experiments made at Geneva, with a similar set on the Col-du-Géant, 10,950 feet higher, Saussure found that, supposing the temperature and dryness of the air the same at both places, the evaporation at the upper would be to that at the lower nearly as 7 to 3; so that a diminution of about one third in the density of the air more than doubled the rate of evaporation. It is well known, that cold is always generated during spontaneous evaporation; that is to say, that water, as

it disappears, carries off a quantity of heat. Dr. Black has rendered it probable, that the quantity of heat which disappears during spontaneous evaporation is as great as that which is required to form water into steam. A wet body is always cooled by exposure to dry air, owing to the evaporation from its surface. Hence, in warm countries, liquors are cooled by wrapping wet cloths round the bottles and exposing them to the air. M. Saussure observed, that the evaporation from the surface of melting snow caused it to freeze again, when the temperature of the air was 4° or 5° above the freezing point. The simplest mode of illustrating the cooling influence of evaporation, is to cover the ball of a thermometer with wet cloth and expose it to the air, when it will be found to indicate a greater or less degree of cold. This, it is true, does not take place if the air be very damp, because there is then no evaporation. Wind tends to promote evaporation, both by communicating its heat to the colder evaporating surface, and also by sweeping away the vapour as it is formed. On the contrary, there is scarcely any evaporation in perfectly still air, unless some substance be present which absorbs the vapour as it forms.

762. *On this principle, Professor Leslie contrived an elegant mode of producing ice in any climate.* A cup with water is placed within the receiver of an air pump, along with some substance which absorbs the vapour. The rate of evaporation is then increased in an astonishing degree, by exhausting the air from the receiver; and the portion of the water which is converted into vapour abstracts so much heat from the remainder, that the latter is speedily converted into ice.

763. *Dew* is a remarkable product of atmospheric moisture. The quantity of aqueous vapour which can exist in a given space, as a cubic foot, is pretty generally believed to be the same, whether there be air present in the space, or nothing but the vapour alone. The quantity is always (*cat. par.*) the same at the same temperature, but it is greater as the temperature is higher; and therefore, supposing the space to be saturated with vapour at a particular temperature, a portion of this will return into drops of water whenever the temperature falls. It is on this principle that a cold body, such as a bottle of liquor, being carried into a warm moist apartment, becomes bedewed on the outside, till, perhaps, the water trickles down its sides: the contact of the cold surface chills the air, which in return deposits a portion of its moisture. Now this is similar to the mode in which moisture is insensibly deposited from the atmosphere on bodies at the earth's surface, and which is known by the name of *dew*. All bodies, placed in still air and exposed to the aspect of a clear sky, are found to become colder than they would be if some screen or awning were interposed between them and the sky. In such circumstances, bodies often become much colder than the surrounding air, which, if sufficiently moist, deposits on them a portion of its moisture or dew. When the temperature is low, the dew is frozen, and forms *hoar frost*.

764. *The radiation of heat* also deserves notice. About the commencement of the present century, Professor Leslie discovered that bodies possess very different powers of radiating heat; and that this depends on the nature and condition of their surfaces. Metals possess this quality in a degree inferior to vitreous bodies, and it is diminished in all of them by polishing the surface. Most fibrous and filamentous vegetable substances are good radiators, as are likewise bodies in general which are bad conductors or bad reflectors of heat. Now the degrees of cooling, which different bodies undergo when exposed together to the aspect of the sky, is observed to follow the same order as that of their radiating powers; and, of course, the order in which they begin to acquire dew, as also the quantity acquired, is regulated by a similar law, as will be seen from what follows.

765. *For the investigation of the causes of dew* we are chiefly indebted to the late ingenious Dr. Wells. The ancients maintained, that dew appears only on calm and clear nights. Dr. Wells found that, in opposite circumstances, very little is ever deposited, and that little only when the clouds are very high. Dew never occurs in nights both cloudy and windy; and if in the course of the night, the weather, from being serene, should become dark and stormy, dew which had been deposited will disappear. In calm weather, more dew will appear if the sky be partially covered with clouds, than if it were quite clear. It often happens, that even before sunset, dew begins to adhere to grass in spots which are sheltered from both sun and wind; for, in clear weather, such spots suffer much from the chilling aspect of the sky, and may often continue to acquire dew during the whole night, and for some time after sunrise. The quantity of dew depends on the moistness of the air, being greater after rain than after long-continued dry weather. It is more abundant, in Europe, with southerly and westerly winds, than with those which blow from the opposite points. The reason of this seems to be the direction of the sea rendering the wind moist; for, in Egypt, dew rarely occurs unless the wind come from the sea. But with a southerly wind, which has passed along the floods of the Nile, dew is usually observed in the Delta five or six days before the inundation. After a long period of drought, Dr. Wells exposed to the clear sky, 28 minutes before sunset in a calm evening, known weights of wool and swan-down, upon a smooth, unpainted, dry fir table about 3 feet in height, and which had been placed an hour before in the sunshine in a large grass field. At 12 minutes after sunset the wool was 14° colder than the air, but had gained no weight. The swan-down was 13° colder than the air, but had got no addi-

tional weight ; nor was it any heavier at the end of 20 minutes longer, but it had then become $14\frac{1}{2}^{\circ}$ colder than the air ; whilst the grass was 15° colder than the air four feet above ground. — From these, and many similar experiments, Dr. Wells concluded that bodies become colder than the neighbouring air *before* they are dewed. — He bent a sheet of paste-board into the form of a penthouse, making the angle of flexure 90° , and leaving both ends open. This was placed one evening, with its ridge uppermost, upon a grass-plat, and, as nearly as could be guessed, in the direction of the wind. On the middle of the spot of grass, sheltered by the roof, was placed 10 grains of wool, and an equal quantity on a spot of the grass fully exposed to the sky. In the morning, the first 10 grains were only 2 grains heavier, whilst the other had gained 16. The wool does not here acquire moisture from the grass by capillary attraction, for the same effect happens if it be placed in a saucer ; nor is it by hygrometric attraction, for in a cloudy night, wool placed on an elevated board scarcely gained any weight.

766. *The quantity of dew varies according to circumstances.* When wool is placed upon a bad conductor of heat, as a deal board, a few feet from the ground, it will become colder and acquire more dew than if laid on the grass. At the windward end of the board, it is less bedewed than at the sheltered end ; because, in the former case, the wind keeps up the temperature nearer to that of the atmosphere. Rough and porous surfaces, as shavings of wood, straw, &c. take more dew than smooth and solid bodies. Raw silk and fine cotton collect more than even wool. Glass, being a good radiator of heat, is much more quickly coated with dew than bright metals, which, indeed, receive it less readily than many other bodies. This circumstance has given rise to the strange idea that metals absorb dew, though they be the most compact bodies known. If we coat a piece of glass partially with bright tin-foil, or silver leaf, the uncovered portion of the glass quickly becomes cold by radiation, on exposure to a clear nocturnal sky, and acquires moisture ; which, beginning on those parts most remote from the metal, gradually approaches it. Thus, also, if we coat a part of the outside of a window pane with tin-foil in a clear night, then moisture will be deposited inside, on every part but that opposite to the metal ; but if the metal be inside, then the outside of the coated part of the pane will be sooner and more copiously bedewed. In the first case, the tin-foil prevents the glass under it from dissipating its heat, and therefore it can receive no dew ; in the second case, the tin-foil prevents the part of the glass which it coats from receiving the calorific influence of the apartment, and hence it is sooner cooled on the outside than the rest of the pane. When the night, after having been clear, becomes cloudy, though there be no change with respect to calmness, a rise in the temperature of the glass always ensues. In clear nights the temperature always falls, but, unless the air be sufficiently moist, dew does not necessarily follow ; from which it is evident, that the cold cannot be the effect of dew. For a more particular account of these interesting phenomena, we must refer the reader to Dr. Wells's elegant *Essay on Dew*.

767. *Clouds.* The various forms of clouds were first successfully attempted to be arranged under a few general modifications by Mr. Luke Howard, and published in the 16th and 17th vols. of the *Phil. Mag.* The system is very simple, and has been extensively adopted both here and on the Continent. In giving a summary of it in "*The Climate of London*," Mr. Howard thus expresses himself : — "After the experience of eighteen years, I do not find a necessity either to make additions to this little system, or to retrench any of its parts. Some subordinate distinctions may, indeed, at a future period be found useful ; but until the classification, as it is, be generally adopted, its simplicity must form its most powerful recommendation, and its conformity to nature. It is in the *form and structure*, carefully considered with due reference to situation, that he will find the basis of a correct judgment ; and he will do well to wait, at first, for several successive appearances of each modification, to which he will thus at length find the definition apply in all its parts."

768. *The modifications of clouds* is a term used to express the structure or manner of aggregation, in which the influence of certain constant laws is sufficiently evident amidst the endless subordinate diversities resulting from occasional causes. Hence the principal modifications are as distinguishable from each other, as a tree from a hill, or the latter from a lake ; although clouds, in the same modification, compared with each other, have often only the common resemblance which exists among trees, hills, and lakes, taken generally.

769. *There are three simple and distinct modifications*, which are thus named and defined by Mr. Howard : —

(1.) *Cirrus.* A cloud resembling a lock of hair or a feather. Parallel, flexous, or diverging fibres, unlimited in their extent or direction.

(2.) *Cumulus.* A cloud which increases from above in dense convex or conical heaps.

(3.) *Stratus.* An extended continuous level sheet of cloud, increasing from beneath.

770. *There are two modifications which appear to be of an intermediate nature* : these are —

(4.) *Cirro-cumulus.* A connected system of small roundish clouds, in close order or contact.

(5.) *Cirro-stratus.* A horizontal or slightly inclined *sheet*, attenuated at its circumference, concave downward, or undulated. Groups or patches have these characters.

771. *There are two modifications which exhibit a compound structure, viz. : —*

(6.) *Cumulo-stratus.* A cloud in which the structure of the *cumulus* is mixed with that of the *cirro-stratus* or *cirro-cumulus*. The *cumulus* flattened at top, and overhanging its base.

(7.) *Nimbus.* A dense cloud spreading out into a crown of *cirrus*, and passing beneath into a shower.

772. *Mr. Howard* began his observations about twenty-five years ago, and *Dr. Thomas Forster* has been for many years employed in making similar observations. From all these, there has resulted at length a theory of the formation and changes of the clouds, which has been deduced entirely from the phenomena they have been observed to exhibit during their formation, changes, and eventual resolution into rain. To avoid, as much as possible, any particular hypothesis as premature, we shall merely give an account of the phenomena observed; contenting ourselves with a description of the distinct modifications of form which aqueous vapour is found to assume during the progress of the formation, changes, and resolution of clouds.

773. *Regarding the mode in which clouds are suspended in the air*, philosophers are not agreed. About the commencement of the last century, it was supposed that the aqueous particles of clouds were in the form of hollow shells, specifically lighter than the air in which they float. But as no evidence or probability could be adduced in favour of this theory, it has given place to other speculations; and, at present, many consider the suspension of clouds as an electrical phenomena. On attentively observing the forms of clouds, it will be found that they have a tendency to assume one or other of the seven distinct modifications above mentioned; the peculiar characters of which may be discovered in all the endless configurations exhibited by clouds under different circumstances. It may be observed farther, that the most indefinite and shapeless masses of clouds, if attentively watched, will sooner or later show a tendency to assume the form of some of these modifications; a circumstance which shows not only their distinct nature, but also proves that there are some general causes, as yet undiscovered, why aqueous vapour, suspended in the air, should assume certain definable and constant modifications.

774. *A more minute description of the formation and changes of the clouds*, and of the prognostics of the weather to be deduced from their peculiar appearances, shall now be attempted.

775. *The cirrus or curl-cloud** may be distinguished from every other by the lightness of its nature, its fibrous structure, and the great and perpetually changing variety of figures which it presents to the eye. It is generally the most elevated of clouds, occupying the higher regions of the atmosphere. As this cloud, under different circumstances, presents considerable varieties of appearances, it will be proper to consider these separately, with reference to the particular kind of weather in which they prevail. After a continuance of clear fine weather, a whitish line of cloud may often be observed at a great height, like a white thread stretched across the sky, the ends seeming lost in each horizon: this is often the first indication of a change to wet weather. To this line of cirrus, others are added laterally, and sometimes, as it were, propagated from the sides of the line in an oblique or transverse direction; the whole having the appearance of net-work. At other times the lines become gradually denser; descend lower in the atmosphere; and, uniting with others below, produce rain without exhibiting the above-mentioned transverse reticulations. The above-described varieties of cloud, though composed of straight lines, are ranged under the general head of *cirrus*, from their resemblance to this cloud when it appears under curved and contorted forms. The *comoid cirrus*, popularly known under the name of the *grey mare's tail*, is the proper cirrus. It somewhat resembles a distended lock of white hair, or a bunch of combed wool, and from this it got the name *comoid*. It usually occurs in variable weather, and is reckoned a precursor of wind and rain. In changeable weather it varies considerably in a few hours; but when the fibres have a constant direction to the same point of the compass for any considerable time, a gale of wind generally springs up from that quarter. During warm changeable weather, when there are light breezes of wind, long and obliquely descending bands of cirrus are often observed in the air, and sometimes seem to connect distant clouds. Frequently, by means of the interposition of these cirri between a cumulus and some other cloud, as, for instance, cirro-stratus, the cumulo-stratus, and ultimately the nimbus or rain-cloud, is formed. The cirrus, when attentively examined, is found to be in constant motion, not merely changing its form, but often exhibiting an internal commotion in the substance of the cloud, especially in the larger end of it. Every particle seems alive and in motion, while the whole mass scarcely changes its place. This motion, on a minute examination, often appears to consist of the fibres which compose the cirrus, gently waving to and from each other; frequently, however, it seems like minute specks all in commotion. This takes place more frequently in those large and lofty cirri, with rounded heads and long pointed tails, so common in dry easterly winds during summer and autumn.

* This, and the other additional terms which follow, have been proposed as English names by Dr. Thomas Forster.

776. *The formation of the cumulus* is best viewed in fine settled weather, about sunrise or a little after. Small specks of cloud are seen here and there in the atmosphere. These seem to be the result of small gatherings of the stratus or evening mist, which rising in the morning grows into small masses of cloud, while the rest of the sky becomes clearer. About sunrise these clouds increase; two or more of them unite, till a large cloud be formed, which, assuming a cumulated and irregularly hemispherical shape, has received the name of *cumulus* or *stacken-cloud*. This is properly the cloud of day, as it usually subsides in the evening by retracing the steps of its formation in the morning. It separates into small fragments and evaporates, giving place to the stratus or fall-cloud, which is therefore styled the cloud of night.

777. *Some varieties in the forms of the cumulus* deserve particular notice, as they are supposed to be connected with electrical phenomena. The hemispherical form is more perfect in fine than in changeable weather. When such well-formed cumuli prevail during many successive days, the weather is settled, and the electrometer pretty steady in its indications. They are whitish coloured, and when opposed to the sun reflect a silvery light. Cumuli which occur during intervals between showers are more fleecy, and variable in form and colour. Sometimes they are blackish, and may at any time increase till they obscure the sky, or assume the form of the twain-cloud or cumulo-stratus.

778. *The stratus or fall-cloud* comprehends fogs, and all those creeping mists which, towards evening fill the valleys, and disappear in the morning. The cumuli which have prevailed during a hot summer's day decrease towards evening, and by degrees there is formed a white mist near the ground, increasing in density till midnight or even till morning, and generally disappearing after sunrise. In autumn, this cloud sometimes lasts longer in the morning. In winter it becomes still more dense, and sometimes continues a whole day or many successive days. A remarkable instance of this occurred in January, 1814, when a dense fog prevailed for about a fortnight, extending over a great part of the south and west of England. It was particularly felt at London, where the stagnation and subsidence of the smoke more than doubled the dismal visitation. The stratus is often positively electrified, and its component parts do not wet leaves or other substances connected with the earth. On this, however, it may be remarked that dry bodies, which continue warmer than the fog, must remain dry on the ordinary principles of evaporation. The stratus may be distinguished from some varieties of cirro-stratus which resemble it, by the circumstance that the latter wets every object it alights on.

779. *The cirro-cumulus or sonder-cloud* is subject to some variations in the size and figure of the orbicular masses of which it is composed, and in their distances from each other. About the time of thunder storms, the component parts are denser in their structure, rounder in their form, and closer together than usual. This has been frequently noticed by poets as a prognostic of thunder and tempestuous weather. In rainy changeable weather, this cloud has a light fleecy texture, and is very irregular in the form of its component parts; so that it then approaches to the form of the cirro-stratus. Sometimes, indeed, it consists of *nebeculae*, so small and light coloured as to be scarcely discernible. In fine summer weather, the cirro-cumulus is neither so dense as the stormy variety, nor so light as the one last described; its parts vary in size, and in their proximity. During fine dry weather, with light breezes from the north and east, small detachments of cirro-cumulus rapidly form and subside, which do not lie in one plane; but their arrangement is commonly horizontal. The cirro-cumulus sometimes commences in the clear sky. At other times the cirrus, the cirro-stratus, or some other cloud, changes into cirro-cumulus, and *vice versâ*. In summer, this cloud forebodes heat: in winter, the breaking up of frost, and mild wet weather.

780. *The cirro-stratus* is remarkable for its shallowness, compared with its horizontal extent; so that when any other cloud assumes this form, it seldom fails to end in a cirro-stratus. This cloud is constantly changing its form, and gradually subsiding; hence it has been called the *wane-cloud*. There are many varieties in its figure; sometimes it is disposed in waving bars or streaks, varying almost infinitely in size and shape. A flat horizontal cloud, consisting of such streaks, frequently occurs during changeable summer weather; its bars are generally confused in the middle, but more distinct towards the edges. A variety of this sort constitutes what is called the mackerel-back sky. It is often very high in the atmosphere, as is proved from its still appearing high when viewed from the top of a lofty mountain. The cumulus, on the contrary, may be seen on a level with, or even lower than, the observer. The cirro-stratus often appears in the form of a long plain streak, tapering towards the extremities. Sometimes such a figure seems to alight on the cumulo-stratus; and, in these cases, the density of the latter increases in proportion as the former alternately appears and evaporates again on its summits. The usual result is the formation of the nimbus, and a fall of rain. Another principal variety of the cirro-stratus consists of small rows of little clouds, curved in a peculiar manner: it is called the *cymoid* cirro-stratus, and is a sure indication of approaching storms. The last variety of this cloud which we shall now notice, is that large and shallow veil of cloud which covers a large portion of the sky, particularly towards night, and through which the sun and moon are indistinctly seen.

Those peculiar refractions of the light of these luminaries, called halos and mock suns, usually appear in this cloud. These are the most certain signs, yet known, of approaching rain or snow.

781. *The cumulo-stratus or twain-cloud* is a stage towards the production of rain, and is frequently formed in the following manner: — The cumulus, which usually passes along in the wind, seems retarded in its progress, grows denser, spreads out laterally till it overhangs the base in dark and irregular protuberances. This change often takes place in all the cumuli which are near to each other; their bases unite, whilst the superstructure remains asunder, rising up like so many mountain summits or masses of rocks. The cumulo-strati, in which hail showers and thunder storms occur, look extremely black and menacing before the rain commences. Sometimes the cumulo-stratus evaporates, or changes again to cumulus, but it oftener ends in the nimbus and rain.

782. *The nimbus* remains to be described; a cloud which always precedes the fall of rain, snow, or hail. Any of the others above described may increase so much as to obscure the sky, without ending in rain, before which the peculiar characteristic of the rain-cloud may always be distinguished. The best way of obtaining a clear idea of the formation of the nimbus or rain-cloud is to observe a distant shower in profile, from its first formation to its fall in rain. The cumulus seems first arrested in its progress; then a cirrus or cirro-stratus may appear to alight on the top of it. The change to cumulo-stratus then goes on rapidly; and this cloud, increasing in density, assumes that black and threatening aspect which is a known indication of rain. This blackness is soon changed for a more grey obscurity; and this is the criterion of the actual formation of rain drops, which now begin to fall, while a *cirriform* crown of fibres extends from the upper parts of the clouds, and small cumuli enter into the under part. After the shower has spent itself, the different modifications appear again in their several stations: the cirrus, the cirro-stratus, or perhaps the cirro-cumulus, appear in the upper regions of the air; while the remaining part of the broken nimbus assumes the form of flocky cumuli, and sails along in the lower current of wind. The reappearance of large cumulo-strati indicates a return of the rain. In showery weather, the alternate formation and destruction of rain-clouds goes on rapidly, and is attended by the other modifications in succession, as above described. From its connection with local showers, the nimbus is distinguished almost exclusively by bearing in its broad field of sable the honours of the rainbow.

783. *Rain.* Theories of rain have been founded on the above observations. Since, as already mentioned, a greater quantity of moisture can exist in a given space as the temperature is higher, it is plain that there is a certain temperature at which air containing some moisture will just be saturated, and which is called the point of deposition, or the *dewing* point; for, if cooled in the least below this, the air will deposit moisture. When the cooling in the body of air below the dew point is very slight, the effect is merely to disturb the transparency, or produce a *fog*. In the case of dew, formerly considered, the transparency is not affected; because it is not the *mass* of air that is cooled below the point of deposition, but only a minute portion of it which comes into contact with surfaces cooled by radiation. When the cooling in a body of air below the dewing point is considerable, the water is deposited more copiously, and, collecting into drops, descends to the earth in the form of *rain*; or if the temperature be sufficiently low, the drops are partially frozen, and form *sleet*; if fully frozen, *snow*; and if such drops be large and compact, they receive the appellation of *hail*.

784. *Dr. James Hutton of Edinburgh* made the first attempt to account for the phenomena of rain, &c. on known principles. Without deciding whether moisture be simply mixed or chemically combined in the air, he conjectured from the phenomena, as is now established by experiment, that the quantity of aqueous vapour which can exist in air varies in a higher ratio than the temperature. Hence he inferred, that whenever two volumes of air saturated with moisture are mixed at different temperatures, a precipitation of moisture must ensue, in consequence of the *mean* temperature not being able to support the *mean* quantity of vapour. But if the air, before mixture, was not fully saturated with moisture, then a smaller quantity, or none at all, may be deposited. This theory has been adopted by various meteorologists, particularly Professor Leslie and Mr. Dalton: but Mr. Luke Howard has justly remarked, that it involves the assumption that the mixture should have the *mean* temperature, — a point which was then, and is even yet, not quite settled; although, so far as experiment goes, it is fully more favourable to the theory than the *mean* would be.

785. *Mr. Howard accordingly rejects Dr. Hutton's theory*, and alleges, that rain is almost in every instance the result of the electrical action of clouds upon each other. This idea, he thinks, is confirmed by observations made in various ways upon the electrical state of the clouds and rain; and he supposes that a thunder storm is only a more sudden and sensible display of those energies which are incessantly operating for more general purposes.

786. *There are two circumstances* deserving of notice in the formation of the nimbus or rain-cloud, the spreading of the superior masses of cloud in all directions, until they become, like the stratus, one uniform sheet; and the rapid motion and visible decrease of the

cumulus, when brought under the latter. The cirri, also, which so frequently stretch from the superior sheet upwards, like so many bristles, are supposed by some to be temporary conductors for the electricity evolved by the union of minute particles of vapour into the larger drops which form the rain. In an experiment of Cavallo's with a kite sent up 360 feet, in an interval between two showers, and kept up during rain, it seems that the superior clouds were positively electrified before the rain; but on the arrival of a large cumulus, a strong negative electricity took place, which lasted while the cumulus was passing over the kite. We are not, however, warranted to conclude that the cumulus which brings on rain is always negative; as the same effect might ensue from a positive cumulus uniting with a negative stratus: yet the general negative state of the lower atmosphere during rain, and the positive indications commonly given by the true stratus, render this the more probable opinion. It is not, however, absolutely necessary to determine the several states of the clouds which appear during rain; since there is sufficient evidence in favour of the conclusion, that clouds formed in different parts of the atmosphere operate on each other when brought near enough, so as to occasion their partial or entire destruction, — an effect which can be attributed only to their possessing beforehand, or acquiring at the moment, the opposite electricities. Such is Mr. Howard's view of the subject; but until electricity itself, and in particular the electricity of the atmosphere, be better understood, it is doubtful if the phenomena of rain be brought any nearer home by being ascribed to electricity. In the present state of science, Dr. Hutton's theory has rather the advantage of depending on principles which are better known, though there is some uncertainty regarding their fitness for the purpose.

787. *Rain is very unequally distributed* to the different regions of the globe; but nature has so arranged it, that it is most copious in those latitudes where evaporation is most rapid. There are, however, exceptions to this rule; for on several tracks on the earth's surface it hardly ever rains. These are usually far inland, and are generally extensive plains utterly sterile and uninhabitable. The want of rain is in some places partially supplied by the copious deposition of dew. On the contrary, there are some spots where it always rains, and which are mostly on the sea. As the whole atmosphere, when fully charged with humidity, is calculated to hold no more water than would form a sheet 5 inches in depth, while the mean annual deposit is about 35 or 40 inches, it is plain that the supply must be frequently renewed. Rain is more abundant toward the equator than the poles, at the sea coast than towards the interior, and on elevated situations than on plains.

788. *From the most authentic sources, Mr. Dalton has constructed the following table, showing the mean monthly and annual quantities of rain which have fallen at several places, being the average for many years: —*

	Manchester. 33 Years.	Liverpool. 18 Years.	Chatsworth. 16 Years.	Lancaster. 20 Years.	Kendal. 25 Years.	Dumfries. 16 Years.	Glasgow. 17 Years.	London. 40 Years.	Paris. 15 Years.	Viviers. 40 Years.

789. *The depth of rain*, according to Humboldt, at the latitudes of 0° , 19° , 45° , and 60° , is, respectively, 96, 80, 29, and 17 inches. In the torrid zone, a small thick rain falls almost every day on that side of the equator where the sun is; but it generally intermits during the night. In many places, there are two wet and two dry seasons in the year; and in some regions, from the effect of mountains and peculiar winds, places under the same parallel have their wet and dry seasons at opposite periods. Though the annual depth of rain be greatest toward the equator, the number of rainy days increases with the latitude.

790. *Aqueous meteors*, so essential to vegetation, have their salutary effects modified by the *chemical qualities* of the moisture in the atmosphere. The salt rain and dew in the vicinity of the Caspian Sea, owing to the vapours which are exhaled from the soil, probably contribute to those saline efflorescences which are said to be gradually overspreading the once fertile soil of Persia. The salt fogs in the west of Jutland are very injurious to the foliage

of trees, without being hurtful to grass. Rain has also been known to be impregnated with sulphur, and with various substances approaching to that of animal and vegetable matters. Some of these communicate to the rain a peculiar colour, as that of blood, &c. On the other hand, fogs occur in which little or no moisture is present: such are called *dry fogs*; and are supposed to be the vapours and ashes ejected by volcanoes, and diffused in the atmosphere by the winds. Their occurring about the time of great eruptions strengthens this conjecture.

791. *Glaciers.* Ice and snow absorb a large portion of heat during liquefaction, which they give out again on freezing; for, in the ordinary process of nature, water does not cool below 32° F. till the whole be frozen; nor does its temperature rise above that point, while in contact with ice or snow,—that is, till the whole be melted. This property has an important effect on the temperature of snowy districts. It retards and often prevents the occurrence of extreme cold, and it opposes a sudden rise of temperature above the freezing point. The cold in the atmosphere, as was formerly stated, continually increases with the elevation; and, at a certain height, depending on the climate or latitude, perpetual frost prevails. Where the earth's surface attains this height, it is, with the exception of some steep or vertical cliffs, continually covered with snow. The snow acquires new additions from time to time; for, though it may melt slowly from the heat of the ground on which it rests, yet it suffers little decay externally, except what the air carries off by evaporation. The warmth of the solar rays may soften it a little, but this only tends to its farther consolidation. Masses of this sort are called *glaciers*. By accumulating in the manner just mentioned, they often become top-heavy, or acquire such an enormous weight as to break their hold, or crush their lower parts, which are besides liable to be undermined by the warmth of the mountain on which they rest. Hence it not unfrequently happens, that huge masses of ice or conglomerated snow slide or roll down the sides of mountains, transporting, perhaps, large stones or fragments of rocks to which they had adhered, or which had been separated from their beds by the agency of the weather. Detached glaciers often descend into districts having a mean temperature considerably above the melting point of snow. But so great is the heat consumed in liquefying such huge masses, that years may elapse before they entirely disappear; and during that interval others descend; and so on continually. So that the limit of perpetual snow may be found in a climate where little snow falls from the clouds. When glaciers descend into the sea, and particularly when detached and floating, they are termed *icebergs*.

792. *The snow-line*, or lower limit in mountains covered with perpetual snow, descends in winter and rises again in summer. Under the equator, this change is scarcely perceptible; but it increases with the latitude, and in high latitudes the snow-line has a great range. The direction of the prevailing winds, with many circumstances too numerous to be detailed, have each its effect. The snow-line is lower on the sides of mountains turned from the sun, than on acclivities which receive his rays more perpendicular to their surfaces. Hence it happens, that one side of a mountain may be covered with perpetual snow, whilst at the same height on the opposite side it is in a state of cultivation. The snow-line, therefore, depends so much on localities, that no general rule can be given for computing its altitude. Though often employed for estimating the heights of mountains, it is a most fallacious criterion.

793. *Humboldt gives the following heights of perpetual snow* in different parts of the world:—Andes of Quito (lat. 1° to $1^{\circ} 30'$), 2460 toises. Volcano of Puracé (lat. $2^{\circ} 18'$), 2420 toises. Tolima (lat. $4^{\circ} 46'$), 2380 toises. Nevados of Mexico (lat. 19°), 2350 toises. Himáláya (lat. 31°), southern side, 1950 toises; northern side, 2605 toises. Summit of Sierra Nevada, Grenada (lat. $37^{\circ} 10'$), 1780 toises. Caucasus (lat. 42° to 43°), 1650 toises. Pyrenees (lat. $42^{\circ} 5'$ to 43°), 1400 toises. Swiss Alps (lat. 46°), 1370 toises. Carpathian mountains ($49^{\circ} 10'$), 1330 toises. Norway (lat. 61° to 67°), 850 to 600 toises; and (lat. 70° to $71^{\circ} 30'$) 550 to 366 toises.

794. *Colour of the Atmosphere.* That the air has a blue colour, has been conjectured because a distant landscape appears of that cast, which, however, is greatly diminished by a good telescope. Newton ascribed this phenomenon to the greater refrangibility of the blue rays; and some consider it the effect of vapour. The appearance of the sky, when viewed from a high mountain, is of a deep blue, approaching to black. But this must be in some way illusory; because the upper atmosphere is highly transparent, as the heavenly bodies shine with increased splendour.

SECT. IV. *Luminous Meteors.*

795. *The refraction and reflection of light* by air produces a remarkable phenomenon. While the rays of light move in a medium of uniform density and composition, they are straight; but when they pass obliquely into a medium of a different density, they are bent or *refracted* toward the denser medium. The rays of light, therefore, whilst coming through the atmosphere from the heavenly bodies, are always entering into a denser and denser stratum of air, and are consequently bent down towards the earth. The different rays suffer different degrees of refraction, according to their colour. That of the red is the least, then

orange, yellow, green, light blue, indigo, and violet. All solid bodies have the property of reflecting light; and it is probable that all bodies whatever reflect light in a greater or less degree. The clouds and air possess this property. The rays which are the most refrangible, are also the most easily reflected. When the sky shines with a fine azure hue, it is by means of the more reflexible rays, which are first reflected from the earth, and afterwards returned by the atmosphere. The refraction and reflection of light enable it to diffuse itself over the atmosphere, illuminating our hemisphere for a considerable time after the sun has gone down and before he has arisen, producing the morning and evening *twilight*.

796. *The rainbow* is a circular image of the sun, variously coloured, and produced thus:—The solar rays, by entering the drops of falling rain, are refracted to their farther surfaces, and thence, by one or more reflections, transmitted to the eye. But on escaping from the drop, they undergo a second refraction, by which the rays are separated into their different colours; and in this state are exhibited to an eye properly placed to receive them. The rainbow is never seen but when rain is falling, and the sun and bow are always on opposite sides of the observer.

797. *The halo* is a broad circle of a variable diameter, sometimes white, but more commonly exhibiting a faint representation of the colours of the rainbow. It appears in a thin cloud, or in a haze, around the sun or moon's disc.

798. *The corona* is a circular space, full of mild whitish light, around the moon's disc. It sometimes passes into a yellowish or brownish colour towards the edges. This and the *halo* are popularly known by the name of *burrs*; and the latter is accounted a prognostic of rain, especially when its diameter is large.

799. *Parhelia* or *mock-suns* are images which appear sometimes above and sometimes below the disc of the true sun. They are supposed to be seated in the points of intersection of different halos, and to derive their brightness from the union of several reflections. *Parhelia* are sometimes surrounded by a whitish border, sometimes by the colours of the rainbow. They are rarely quite circular, and some have luminous trains, as has likewise the sun himself, when near the horizon, in the vicinity of Hudson's Bay. It is there, and in similar cold foggy situations, that *parhelia* are usually seen.

800. *Mock-moons* or *paraselenæ* are of less frequent occurrence than *parhelia*, but they are generally ascribed to a similar cause.

801. *Luminous shadows* or *glories* are remarkable phenomena, in which a spectator sees his shadow projected on a cloud with a luminous ring, sometimes coloured like the rainbow, encircling his head. The spectator, in such cases, must either be on an elevation, or the cloud must be very low. The shadow is usually of an enormous size.

802. *Looming* is the term used by our sailors to express a curious optical deception, by which objects come into view, though materially altered as to their real situation or position. The French call it *mirage*, and the Italians *fata morgana*. It often happens at sea, that a distant ship appears as if painted in the sky, perhaps in an inverted position, and not supported by the water. Sunken rocks and sands appear as if raised above the surface. The Swedes long searched in vain for an illusory island of this sort, which they saw from a distance, as if placed between the isles of Aland and the coast of Upland. The shipping and buildings on the shore of Naples have, from Messina, sometimes appeared floating inverted in the air. In 1798, the terror of the enemy was not a little increased by the appearance of the French coast distinctly raised above the sea, for an hour, as viewed from the opposite shore of Sussex. To the French, whilst marching in the Egyptian deserts, the sandy plain covered in the distance by a dense vapour presented the illusive image of a vast lake, towards which they hastened, but could never reach it.

803. *The aurora borealis*, or *northern light*, is a remarkable luminous phenomenon which occurs during night, and most commonly in clear or frosty weather. It is unknown in low latitudes, and becomes more frequent as we recede from the equator. But it is doubtful if its maximum either as to frequency or brilliancy be at the pole; for in the late north polar expeditions it was seen to the south of the observer, whereas at greater distances from the pole it appears to the north or a little to the west of north of the spectator. It is usually of a reddish colour, inclining to yellow, and sends out frequent coruscations of pale light, which seem to arise from the horizon in pyramidal undulating forms, and shoots with great velocity towards the zenith. Some maintain that a whizzing noise accompanies this phenomenon, but that is not very well ascertained. The light appears sometimes remarkably red, as was the case in many parts of Europe, Dec. 5. 1737. The *aurora borealis* frequently appears in the form of a luminous arch, chiefly in the spring, and in the autumn of a dry season. The arch is partly bright and partly dark, but generally transparent. This kind of meteor is almost constant during the long winter nights, in high latitudes. The "merry dancers," as it is called in Shetland, afford the inhabitants great relief amid the gloom of their long dreary nights. They commonly appear at twilight near the horizon, of a dun yellow, and sometimes continue so for several hours, without motion; afterwards they break into streams of a stronger light, passing into columns and innumerable different shapes. During this, the colour varies from all the tints of yellow to the most obscure russet, exhi-

biting the most beautiful appearance. In the northern parts of Sweden and Lapland, the aurora borealis is singularly beautiful, and affords to travellers a very fine light during the whole night. In Hudson's Bay it diffuses a variegated splendour sometimes equal to that of the full moon. Similar lights were observed by Dr. Forster towards the south pole, but they were much feebler than in the northern hemisphere. The cause of such phenomena is unknown. Some ascribe them to electricity and magnetism.

804. *The electricity* of the atmosphere is very imperfectly understood. In storms, the clouds usually exhibit the vitreous or positive electricity. In summer, when the earth is dry, and the day warm and serene, the electricity of the air increases from sunrise to noon; in which state it continues for an hour or two, and again diminishes, till the dew appear. It revives towards midnight, and again decreases till it become insensible.

805. *The phenomena of thunder* are so well known, as to require no description; but no satisfactory explanation has yet been discovered, except that it is intimately connected with electricity, which being itself in a great measure among the *incognita*, leaves us still in the dark. Thunder is more frequent as we approach the equator, and decreases as the latitude increases, being totally unknown in the arctic regions. It is a very rare phenomenon in intensely cold weather, and seldom occurs during night in the temperate zones. It is usually attended by heavy showers of hail or sleet, and less frequently by rain. The distance of thunder may be estimated, by allowing 1100 feet for each second which elapses between seeing the flash of lightning and hearing the report. It is seldom heard at a greater distance than two miles, and only does mischief when very near.

806. *St. Elmo's fire* is a faint light which seems to adhere to the points of bodies carried swiftly through the air. It appears on the tops of ship masts, and at the points of spears and other warlike instruments when in motion. It is generally believed to be an accumulation of electric matter. A single flame of this sort was called by the ancients *Helena*. When seen in pairs, they were called *Castor* and *Pollux*. A friend travelling towards the Lead Hills in Scotland observed his fingers, his switch, and the ears of his horse, ornamented with lights of this description during wet weather.

807. *Fire-balls* are those luminous bodies which appear usually at a great height above the earth, and were on that account long known by the term *meteor*, which is now applied to many other aerial phenomena. They present a very imposing appearance, and are seen of an immense size, sometimes red, but oftener of a vivid dazzling white. They traverse the atmosphere with amazing velocity. This, and their great height, have been inferred from their being seen from various distant places almost at the same instant. Sometimes they burst in pieces, or discharge torrents of flames, with a detonation making both the air and earth to tremble. Some of these balls descend like lightning, break through the roofs of buildings, destroy animals, and shatter vessels at sea; in short, they are often attended with all the disastrous effects of thunder and lightning, with which they are occasionally accompanied. Some consider these balls to be great masses of electric matter, passing from one place to another. Others suppose them to be the same with the *aërolites*.

808. *Aërolites*, or *meteoric stones*, have frequently descended from the atmosphere from the remotest antiquity. Both the above opinions may be in so far correct; because the fire-balls exhibit very different appearances. Philosophers are very much divided regarding the origin of meteoric stones. Some imagine them to be ejected from volcanos on the earth's surface; others from volcanos on the moon. A third class maintain, that they are generated by the combination and condensation of their component parts, previously diffused in the atmosphere in the gaseous form. Others allege, that they are detached stones moving through the boundless regions of space, and which casually come into contact with our planet. All these are little else than conjecture, although their formation in the atmosphere is the most plausible. A numerous list of the most authentic falls of such bodies is given in *Phil. Mag.* vol. lxvii.

809. *Falling stars* are very ordinary phenomena every where, but still they belong to a class which is not well understood. Near the place of their apparent descent, a fœtid gelatinous substance has frequently been found, of a whitish yellow colour.*

810. *The zodiacal light* is a luminous appearance, seen after sunset, or before sunrise, somewhat similar to the milky way, but of a fainter light, in the figure of an inverted cone or pyramid, with its base towards the sun. Its axis is variously inclined to the horizon, and makes an angle of nearly 7° with the plane of the ecliptic. The earliest distinct account of it was given by Cassini in 1683; but this affords no ground for supposing that it had not existed or been seen prior to that date: it is always observable, when the sky is clear, in the torrid zone; but is more rarely to be found as we recede from the equator. The season most favourable for observing it is about the beginning of March: it is much brighter in some years than others, and was particularly brilliant at Paris, 16th February, 1769. The zodiacal light lies in the plane of the sun's equator, and is therefore supposed by some to be connected with his rotation.

* Professor Brandes, of Breslau, has published a curious Treatise on Falling Stars, to which we may direct the attention of our readers.

SECT. V. *Winds.*

811. *Winds* are currents of air occasioned by the disturbance of the equilibrium of the atmosphere by the unequal distribution of heat. The general tendency, in such circumstances, is for the heavier columns to displace the lighter; and for the air at the earth's surface to move from the poles toward the equator: in consequence of the rotation of the earth on its axis, another motion is combined with the currents just described. The air, which is constantly moving from points where the earth's motion on its axis is slower to those where it is quicker, cannot have precisely the same motion eastward with the part of the surface over which it is passing, and therefore must, relatively to that surface, acquire a motion somewhat westerly. The two currents, therefore, from the opposite hemispheres, will, on meeting, about the equator, destroy that part of each other's motion which is in the direction of the meridian, leaving nothing but their united motion towards the west. Such is the cause of the *trade-wind*, as proposed and rejected by Dr. Halley: it was shortly after revived by Hadley, and is pretty generally received. The trade-wind (with certain exceptions) blows constantly from the east, between the latitudes of 30° N. and 30° S.; it declines somewhat from due east, towards the parallel to which the sun is vertical at different seasons of the year. The only supply for the air constantly abstracted from the higher latitudes must be made by a counter current, in the upper regions of the atmosphere, carrying back the air from the equator towards the poles. In a zone of variable breadth, within the region of trade-winds, calms and rains prevail, caused probably by the mingling and ascending of the opposite currents. High lands change or interrupt the course of the trade-winds: thus, under the lee of the African shore, calms and variable winds prevail near the Cape Verd islands, while an eddy, or counter current of air from the south-west, is generated under the coast of Guinea. The lofty barrier of the Andes shelters the sea on the Peruvian shores from the trade-winds, which are not felt till a ship has sailed eighty leagues westward; but the intervening space is occupied by a wind from the south. In the Indian ocean, the trade-wind is curiously modified by the surrounding land: the southern trade-wind blows regularly from the east and south-east, from 10° to 23° south latitude; but between 10° south and the equator north-west winds prevail from October to April, and south-west the rest of the year; while north of the equator, the wind is south-west in summer, and north-east in winter: these are called *monsoons*, but are not fully understood.

812. *As to the parts of the globe that lie beyond the region of trade-winds*, calms prevail pretty generally over a narrow space; beyond which, the region of variable winds extends probably to the poles. Mr. Forster observes, that beyond the tropics the west winds are most common. He also supposes that east winds have an ascendancy within the antarctic circle. According to Robins, a westerly wind almost constantly prevails about latitude 60° S. in the Pacific Ocean. In Hudson's Bay, westerly winds prevail during three fourths of the year, as also in Kamschatka. At Melville island, the north and north-west winds prevail: on account of these winds, the Atlantic may be crossed eastward in about half the time of returning westward.

813. *Sea and land breezes* arise from the same general principle which chiefly occasions the trade-winds: during the day, when the sun renders the surface of the land warmer than that of the sea, the warmer rarified air of the land ascends, being buoyed up and displaced by the heavier air rushing from the sea, and thus forming the *sea breeze*; but the reverse often happens during the night, when the surface of the land becomes colder than the sea, and occasions a wind from the land, or a *land breeze*. Winds of this sort are more frequent about islands and small peninsulas than in other situations; but they are not confined to any particular latitude.

814. *A variety of local winds* have also been observed. The *etesian*, which is a northerly or north-easterly wind, prevails very much in summer all over Europe. Pliny describes it as blowing regularly in Italy for forty days after the summer solstice. It is supposed to be a part of the great lower current moving towards the equator. Another northern wind, which often continues about a month in February and March, is called the *ornithian* wind, because some birds of passage then make their appearance in the south of Europe. A *squall*, or sudden gust of wind, is common in many places; and when its impetuosity is sufficient to bear along trees, buildings, &c., it is called a *hurricane*: such winds have frequently a whirling motion, and are accompanied with torrents of rain or hail, and even thunder; these are sometimes called *tornadoes*: they are principally confined to the torrid zone. The *sirocco* is a hot southern wind, known on the shores of the Mediterranean; when it reaches Naples and Sicily, it is very moist and relaxing to the human frame. Some warm climates are occasionally visited by excessively hot pestilential winds, generally from the south, and known under a great variety of names in different quarters. Such are the *kamsin* of Egypt, the *simoom* or *samiel* of Arabia and the Desert. The deleterious effects, which frequently cut off whole hordes or caravans, are sometimes ascribed to the predominance of one of the component gases of the air, or to a mixture of nitrous gas, &c.; but this is not well ascertained. The very arid state of the air, bearing along vast quantities of burning sand and dust, must of themselves be very prejudicial to animal life. The *harmattan* is a warm, dry, east wind, which occurs in Guinea, and is also of an unwholesome description.

815. *The velocity of the wind* varies from nothing up to 100 miles in an hour; but the maximum is variously stated by different authors. According to Smeaton, a gentle breeze moves between 4 and 5 miles per hour, and has a force of about 2 ounces on a foot; a brisk pleasant gale moves from 10 to 15 miles, with a force of 12 ounces; a high wind, 30 to 35 miles, with a force of 5 or 6 pounds; a hurricane, bearing along trees, houses, &c. has a velocity of 100 miles, and a force of 49 pounds on the square foot.

816. *The force of the wind* is nearly as the square of the velocity multiplied by the density of the air. Some interesting experiments are described by Colonel Beaufoy, *Annals Phil.* vol. viii. p. 94.

817. *The atmosphere is the vehicle of sound*, and we shall close this brief sketch by noticing this property. Till lately, the velocity of sound used to be greatly over-rated. From the experiments of Dr. Moll, in the plains of Utrecht, in 1823, it appears, that the mean velocity of sound is nearly 1100 feet per second; but it varies a little with the temperature and humidity of the air. See *Phil. Trans.* for 1824.

CHAP. II.

HYDROLOGY.

818. *This branch of natural history makes us acquainted with the various properties and relations of the waters of the globe.* Any definition of water is unnecessary; but mankind must have remarked, at a very early period, that the waters distributed over the globe differ considerably in their fitness for drinking, for preparing food, and for other domestic purposes. These differences are occasioned by the foreign bodies which this liquid holds in a state of solution or suspension; for water is capable of dissolving a greater number of substances than any other fluid. Hence it is scarcely ever found native in a state of absolute purity: in some cases, the quantity of foreign matter is so minute, as to have little influence on the taste or other properties; but in other instances they are so abundant, as to render it unfit for common use, or even noxious; while at other times it is medicinal, &c., according to the nature of the substances with which it is impregnated. Native water, free from colour, is almost never poisonous, especially if it be at the same time tasteless; but if blue from copper, green from iron, or brown from vegetable impregnation, it is unfit for the use of man. Water performs the most important functions in the vegetable and animal kingdoms, and enters largely into their compositions, as a constituent part.

819. *The substance of water presents itself under three different forms of aggregation.* If under sufficient pressure, it is liquid at all temperatures above 32° , so far as is known. It is densest at the temperature of 40° . When cooled down to 32° , it ordinarily assumes the solid form of ice; but if great care be taken to avoid agitation, it may be cooled almost to zero, without freezing. Congelation commences in the form of prismatic crystals, crossing each other at angles of 60° or 120° , and the temperature, however low before, instantly rises to 32° . During this process, the mass expands with a prodigious force, the volume suddenly increasing about a ninth part. Glass bottles filled with water, and properly stopped, are burst during its congelation, and the same has happened to a strong bomb-shell. Water passes into vapour at all temperatures, and under any pressure; when the elasticity of the vapour equals or exceeds the incumbent pressure, the process proceeds with violence, and is called boiling. Under the ordinary pressure of the atmosphere, this takes place at about 212° of Fahrenheit's scale; but the boiling temperature varies with the pressure: hence, water boils at a lower temperature on a mountain top, and at a higher in a deep pit.

820. *The relations of water to heat* are very remarkable. With the exception of hydrogen gas, it absorbs more heat in warming, and parts with more in cooling, than other bodies do. Hence, large bodies of water have a powerful influence in checking or retarding sudden alterations of temperature in the surrounding air. Ice, in melting, absorbs as much heat as would raise its temperature 140° , and gives out the like quantity again in freezing,—a property that enables it to resist or retard sudden alterations of temperature in cold climates, in a more remarkable degree than the other; which, however, exerts its influence in the torrid and temperate as well as in the frigid zone. Lastly, water, in assuming the elastic form, absorbs heat sufficient to raise its temperature 1000° , and parts with as much during re-condensing into water; so that water possesses an almost boundless influence in tempering climate.

821. *Water, as to its composition*, was long ranked among the simple elements; but the researches of modern chemistry have ascertained that it is a compound of 88.9 of oxygen, and 11.1 hydrogen; or its composition by volume and weight may be thus stated: one volume of oxygen combined with two of hydrogen, or eight parts by weight of oxygen, with one of hydrogen. It is composed and decomposed, during many of the operations of nature, and its chemical agency is almost universal. It is an ingredient in most bodies which appear under the crystalline form.

SECT. I. *The Ocean.*

822. *The ocean* is the origin and fountain of all the other waters which occur, in whatever form, on the face of the globe. According to some naturalists, it forms the remains of the menstruum or chaotic fluid, in which all solid bodies were originally held in a state of solution, and from which they have been precipitated or crystallized, in short, brought to their present state, during the countless ages which these processes are supposed to have occupied, anterior to the creation of man: be this as it may, we are certain, that it is from the vapours exhaled by the ocean that the atmosphere is furnished with sufficient moisture to support and refresh the organized beings which inhabit the earth. All nature languishes when the atmosphere withholds its rain and dews; plants fade and droop; animals feel their strength failing; even man himself, breathing nothing but dust, can with difficulty procure shelter from the sultry heat by which his frame is parched and overpowered. The ocean is the grand thoroughfare of commerce, forming a medium of communication between the most distant and otherwise inaccessible portions of the earth. It consists of one continuous fluid, spread round the land, and probably extending from pole to pole. All the gulfs, all the inland seas, form only portions detached, but not entirely separated, from that universal sea, denominated the ocean. Geographers roundly estimate the ocean and its branches to occupy three fourths of the entire surface of the globe. But to ascertain the exact proportion between the land and water will afford them ample employment for ages to come, though every day adds to the stock of information already acquired.

823. *The ocean is variously subdivided* by different authors: it may be conveniently divided into five great basins.

824. *The Pacific*, so named from its comparative tranquillity, and often called also the Great South Sea, separates Asia from America. It is the largest of the basins, and somewhat exceeds the entire surface of dry land. Its greatest extent, from east to west, is about 3700 leagues, and breadth 2700. It is bounded on the east by the western and north-west shores of America, and on the west by the eastern coasts of Asia: on the western side, and between the tropics, its surface is studded with innumerable groups of islands, all remarkably small; and consisting generally of coral reefs, rising up like a wall from unknown depths, and emerging but a very little above the sea. These islands are the works of innumerable minute insects, whose incessant labours are thus gradually forming new lands in the bosom of the ocean. On the western side, it communicates with the inland seas of Japan and Otchosc, the Yellow and Chinese seas; and on the eastern side, it has the inlets of California and Queen Charlotte's Sound. The small isles of the Pacific, scattered over the torrid zone, have their temperature so moderated by the ocean as to enjoy the most delightful climate in the world.

825. *The second basin, or Atlantic Ocean*, is usually divided into the North Atlantic, and the South Atlantic, or Ethiopic Ocean. The Atlantic is bounded on the east by Europe and Africa; and on the west, by America: that part of it between Europe and North America is frequently called the Western Ocean. The Atlantic basin extends from 70° N. to 35° and 50° S. latitude; but it is only about half the size of the Pacific Ocean. The length is about 2800 leagues, but the breadth, which is very unequal, varies from 600 to 1800. The South Atlantic contains few islands of any size, and no inlets of consequence; but the North Atlantic abounds in large islands, and in deep and numerous inland seas, which penetrate far on each side into both the old and new worlds, and have fitted it for the most extensive commerce on the globe. On its eastern shores it receives few large rivers; but on the west it receives the Plata, Orinocco, Amazons, and Mississippi, — the largest rivers on the globe. On its eastern shores it receives few large rivers except the Niger; but on the west it receives the Plata, Orinocco, Amazons, and Mississippi, — the largest rivers on the face of the earth.

826. *The third basin is the Indian Ocean*, which washes the shores of the south-east coasts of Africa and the south of Asia. It is bounded on the east by the Indian islands, New Holland, and New Zealand: its length and breadth are each about 1500 leagues: it contains many islands, the two large bays of Bengal and Oman, with the deep inlets of the Persian Gulf and Red Sea. The half-yearly winds called monsoons prevail in its northern parts.

827. *The fourth basin is the Arctic Ocean*, an immense circular basin, surrounding the North Pole, and communicating with the Pacific and Atlantic by two channels; the one separating America from Europe, the other America from Asia. Few points of the coasts of Europe and Asia, which occupy a full half of the circumscribing circle, extend much beyond the 70th parallel; and it is doubtful if the other boundaries, consisting of the northern coasts of America and Old Greenland, reach nearer the Pole; so that the mean diameter of this basin may be taken at 800 leagues. Its interior or central parts are little known: several islands are scattered over its southern extremities, the largest of which is Old Greenland, whose northern limit is unknown; the others are Spitzbergen, Nova Zembla, the Isles of New Siberia, those lately discovered by Captain Parry, and several towards Baffin's Bay. The White Sea, on the north coast of Europe, is the only deep gulf connected with this basin, which is of any importance to navigation.

828. *The fifth basin is the Antarctic*, which is still less known than the preceding: it joins the Pacific in the latitude of 50° S., and the Indian Ocean in that of 40°. Floating

ice occurs in every part of it; but it is very abundant within the parallel of 60° . It was long supposed, that a large continent of land and fixed ice occupied the greater part within the antarctic circle. In 1819, Captain Smith discovered land lying between the longitudes of 55° and 65° W., and beginning at the latitude of 62° . Mr. Weddell has since examined this quarter nearer the Pole, which he believes to be free from fixed ice.

829. *Of the inland seas*, the Mediterranean is the largest and the most important: it is deserving of notice on various accounts, and in particular as having been the scene of by far the greater number of the nautical adventures of antiquity. It is the "Great Sea" of the Sacred Writings, though we find it there spoken of under other names. Its greatest length, from east to west, is about 2350 miles; and the breadth, which is sometimes small, is at the greatest 650. It is bounded on the south by Africa, on the east by Asia, and on the north by Europe. It communicates on the west with the Atlantic by the Straits of Gibraltar, and with the Black Sea by the Dardanelles Strait on the east. It has many islands, gulfs, and bays, with a very deep inlet on the north called the Adriatic Sea, or Gulf of Venice. The Black Sea is connected with the Sea of Azof; but these containing only brackish water, and being so far inland, have more of the character of lakes than branches of the ocean. Proceeding still farther eastward, we come to the Caspian Sea, which is abundantly salt, and of great dimensions; but being wholly unconnected with the ocean, will be afterwards spoken of under the character of a lake. Traces of a connection having once existed between it and the Sea of Azof are said to be visible along the intervening low country.

830. *The Baltic* is pretty much allied to the Black Sea, in having only brackish waters, which are sometimes wholly frozen over for several months in winter, and the ice so strong, that armies have been marched across. The Baltic communicates with the German Sea by the strait called the Cattegat: its greatest length is 1200 miles. The North Sea, or German Ocean, is bounded by Britain and the Orkneys on the west, and the continent of Europe on the east; and reaches from the Straits of Dover to the Shetland Islands, where it joins the Northern Ocean. It was probably, formerly, an inland sea or lake. On the west of the Atlantic are the Gulf of St. Lawrence, Hudson's and Baffin's Bays; but we must now proceed to treat of the different properties and relations of the ocean, so far as our limits will permit.

831. *The usual colour* which sea water exhibits is a bluish green, of various shades. Some maintain, that this is its true and proper colour; others, that it is an optical illusion, occasioned by the greater refrangibility of the blue rays of light, — opinions which may both be true to a certain extent. The ocean seems often to assume various other colours; some of them no doubt real, but as often illusory. Among the more general sources of deception, may be reckoned the aspect of the sky: thus, an apparently dark-coloured sea is a common prognostic of an approaching storm; not that the water is really blacker than usual, but because the dark colour of the clouds indistinctly seen in, or reflected from, the waves, is mistaken for the colour of the sea itself. Whatever other colour the sky happens to wear has a greater or less influence on the appearance of the ocean: thus red clouds seem to tinge it red, &c. On some occasions, the edges of the waves, by refracting the solar beams like a prism, exhibit all the brilliant colours of the rainbow, which is still more nearly imitated by the refraction of the rays in the spray. Not unfrequently, an indistinct image of the neighbouring coast reflected from the ruffled surface is mistaken for the colour of the water.

832. *The variety of colours* in the sea may probably arise from animal and vegetable matters diffused through the waters in a putrescent state, and communicating various tints. The yellow and bright green shades seem to be owing to living marine vegetables, which grow at the bottom, stretch their fibres through the water, or spread over the surface; and it is supposed that the colour of innumerable minute animals is often confounded with that of the sea. Near the shore, and especially towards the mouths of rivers, the diffusion of mud and other earthy matters cannot fail to affect the colour of the sea: where it is shallow or very transparent, the colour of the bottom is frequently mistaken for that of the water.

833. *The colour of the Greenland Sea*, according to Mr. Scoresby, varies from ultramarine blue to olive green, and from the most pure transparency to great opacity. These appearances, he thinks, are not transitory, but permanent; not depending on the state of the weather, but on the quality of the water. Hudson, in 1607, noticed these changes, and observed that the sea was blue where there was ice, and green where it was open. This, however, was only accidental. Phipps does not mention the green water; it forms, perhaps, one fourth of the Greenland Sea, between the latitudes of 74° and 80° ; often it constitutes long bands or currents, lying north and south, or N. E. and S. W. In 1817, the sea was blue and transparent about the latitude of 74° or 75° , and between the longitudes of $0^{\circ} 12'$ and 12° E. In 1817, Mr. Scoresby sometimes passed through stripes of pale green, olive green, and transparent blue, in the course of ten minutes. The food of the whale occurs chiefly in the green water, and there the fishers look for them. Whales are more easily taken in the opaque green water than in the transparent blue, because they do not readily see their enemies through the former. On examining the differently-coloured sea waters, Mr. Scoresby found various substances and animalcules, especially in the olive-green water. The number of

medusæ was immense: they were about one fourth of an inch asunder. Hence a cubic foot would contain 110,592. From these, and many similar observations, Mr. Scoresby concludes, that the Arctic Sea owes its colour to animalcules, and that they occasion the opacity of the olive-green water. The blue water contains few animalcules, and is uncommonly transparent. The surface of the Mediterranean sometimes appears of a purple tint. In the Gulf of Guinea, the sea is sometimes white; and around the Maldivé islands, black. The Vermilion Sea, near California, is so named from its red appearance.

834. *The transparency of the sea* may in many places be very great, without such property being readily noticed. Thus, where the water is sufficiently deep to be dark at the bottom, it may seem quite opaque, unless some fish or other object happen to come within view. Agitation of the surface will likewise tend to conceal the transparency. In general, the sea is more transparent as we recede from the shore, and in cold climates than hot; owing, perhaps, to the smaller quantity of organic matter diffused in the waters of high latitudes. From this, however, there are exceptions; as in the opacity of the Arctic Sea just noticed, and in the case of the Caribbean Sea, which is often remarkably transparent. Admiral Milne observed the bottom at a depth of 150 feet in the Caribbean Sea. Authors are not agreed to what depth the solar rays penetrate; and indeed we have every reason to suppose that this must depend upon and be as various as the transparency. Some limit the penetration to a depth of 100 yards; while others more than double that quantity. The light should surely penetrate to at least double the depth to which an observer can see from the surface.

835. *The temperature of the sea* has probably a tendency to follow the mean temperature of the climate; but many powerful causes must interfere and modify it. Thus, between the tropics, the mean temperature of the surface of the ocean is about 80° , and generally ranges between 77° and 84° . Beyond the tropics, it begins to decrease, but without observing any strict connection with the latitude; because, on account of the great specific heat of water, powerful currents cannot fail partially to preserve, for some time, the temperature of the place from which they come. Hence, currents from the torrid zone, on passing into higher latitudes, raise the temperature of the sea above what usually belongs to such parallels; the reverse holds of cold icy currents from the arctic regions. The temperature of the ocean is much more steady than that of the superincumbent air, and has likewise a smaller annual range: unless where very shallow, it has scarcely any diurnal range.

836. *The temperature of the sea on descending below the surface* generally decreases, but not according to any uniform or known law. Thus, at a depth of five fathoms, it is sometimes 1° colder, while in other instances it requires 100 fathoms for 1° . Sometimes the cold attains its maximum at a depth of 100 fathoms, and sometimes it requires 400 or 500 fathoms. According to an experiment related by Capt. Sabine, the temperature of the Caribbean Sea was 45.5° at a depth of 1000 fathoms, while its surface was 83° . But the enormous pressure at the bottom probably compressed the ball of the thermometer, and kept the apparent temperature 45.5° above the truth. In the Arctic Sea, however, the temperature increases with the depth. Mr. Scoresby, who first ascertained this, found an increase of 6.6° and 8° at the respective depths of 120 and 730 fathoms; Capt. Parry, 6° at 240 fathoms; Capt. Sabine, 7.5° at 680 fathoms; Lieut. Beechy, 10° at 700 fathoms; and Mr. Fisher, 9.5° at a depth of 188 fathoms. Thus, the rate of increase of temperature in the Arctic Sea has as inconstant a connection with the depth as the decrease in the temperate and torrid zones. Sea water freezes about 28° ; after which, the ice has been observed to cool down to -55° ; but we cannot thence infer, that a lower temperature does not occur in the polar regions.

837. *The phosphorescence of the sea* is a common but very remarkable phenomenon, concerning the cause of which authors are not agreed. But most probably, as Newton conjectured, it proceeds from a variety of causes. Since his time, it has engaged the attention of many eminent philosophers. The appearance of these lights is by no means uniform. Sometimes a vessel, in traversing the ocean, seems to mark out a trace of fire; while each stroke of an oar emits a light, sometimes brilliant and dazzling, at other times tranquil and pearly. These lights are grouped in endless variety. Perhaps, at one time, innumerable shining points float on the surface, and then unite into one extensive sheet of light. At another time, the spectator fancies he sees large sparkling figures, like animals in pursuit of each other, incessantly vanishing and re-appearing. Such lights have been ascribed to luminous animals, and to the phosphorescence of semiputrescent matter diffused in the ocean. It is well known, that various fishes and other marine animals emit light, which does not in every instance appear to be voluntary, or to depend on the vital principle, as, in some of them, it continues, and perhaps increases, after death: but motion seems to be either a principal cause, or at least an exciting one; for this light more rarely occurs, and is much fainter, in still water, whilst it becomes more and more brilliant as the motion increases. It is also more abundant immediately before and during storms. In vol. v. p. 303. of the *Edin. Phil. Jour.*, Dr. Francis Buchanan has given a very interesting account of an extraordinary shining of the sea, which he observed, 31st July, 1785, in longitude

61° 25' E., latitude 6° 32' N. "About a quarter past seven P. M.," says he, "the sea was observed to be remarkably white. The sky was every where clear, except around the horizon, where, for about 15°, it was covered with a dark haze, as is usual in such latitudes. The whiteness gradually increased till past eight. The sea was then as high-coloured as milk, not unlike the milky way, the luminous appearance very much resembling the brighter stars in that constellation. It continued in this state till past midnight, and only disappeared as daylight advanced. The whiteness prevented us from being able to see either the break or the swell of the sea, although both were considerable, as we knew from the motion of the ship and the noise. There was much light upon deck, as we could discern all the ropes much more distinctly than usual. We drew several buckets of water, in which, even when at rest, there appeared a great number of luminous bodies. The bulk of them did not appear to be more than one quarter of an inch in length, and nearly as much in breadth. Some, however, were one inch and a half long, and of the same breadth as the others. These were seen to move in the same manner as a worm does in water. When taken up on the finger, they retained their shining faculty even when dry. When brought near a candle, their light disappeared; but, by minute attention, an extremely fine white filament could be observed and lifted upon the point of a pin. It was of a uniform shining colour and form, and about the thickness of a spider's thread. In a gallon of water there might be about 400 of these animals emitting light. The water itself, when in the bucket, had a natural appearance. The atmosphere was seemingly free from fog. The stars were bright, and there was no moonlight. The night before, the same appearance was observed at ten P. M.; it lasted only 20 minutes; but as I was below, I did not hear of it till it was over." — "The animalcules which occasion the unusual luminousness of the sea emit light only when strongly agitated, and hence appear close by the sides of the ship, or when any larger fish passes swiftly, or when a bucket of water is drawn and suddenly poured out." — "In the year 1805, on returning from St. Helena to England, a little north from the equinoctial line, and near the coast of Africa, I had an opportunity of seeing a still more splendid appearance of the luminous animalcules. Soon after dark in the evening, it being nearly calm, we saw numerous lights at a distance, like the lamps of a great city. The lights gradually approached the frigate, and on reaching us appeared to arise from a great many large fishes (albicores) sporting in the water, and agitating the animalcules, so as to excite their luminous powers."

838. *The depth of the sea* is a question on which our information is very imperfect, and there is little likelihood that much accurate information will ever be obtained on the subject, so far as regards the wide ocean. According to the speculations of the late celebrated Marquis Laplace, the depth of the ocean is comparatively small, and nearly uniform. If, however, it be recollected that the bottom of the sea is still a part of the earth's surface, and by much the greater part too, one would be apt to ask, why that larger part of the surface should be more level than what appears as dry land? The soundings which have been made in the ocean are quite inadequate to decide the question. They, however, often indicate great inequalities in the depth; but how far hollows may have been filled with *débris*, or asperities worn down, it is not easy to say; though it is more likely that the summits of mountains exposed to the alternate or combined actions of air and moisture suffer a more rapid abrasion than those which are wholly under water. In general, the slope of the adjacent shore is continued downward for a good way under water; that is, the sea is usually shallow where the shore is flat, while its depth increases rapidly by the side of a cliff or steep mountain. It is therefore probable, that some islands, though very small, may be the tops of sub-marine mountains as large, perhaps, as the highest which occur on the earth's surface. In many instances, no bottom has been found; but this might proceed either from the shortness of the line, or from its being borne aside by rapid currents. We have already mentioned a sounding of 6000 feet in the Caribbean sea; but Lord Mulgrave's line of 4680 feet did not reach the bottom of the Northern Ocean. In the entrance of the German or North Sea, at the Straits of Dover, the central depth is 29 fathoms. This extensive basin contains various shallows and sand-banks; yet, generally speaking, the depth increases in going northward, and near to Bergen in Norway it amounts to 190 fathoms. A very interesting account of the bed of the German Sea is given by Mr. Stevenson, *Edin. Phil. Jour.* iii. 42.; and in the third volume of the *Memoirs of the Wernerian Society*.

839. *The level of the open sea* is believed, generally speaking, to be every where the same; or to form a portion of the surface of an oblate spheroid, to which the surface of the land approaches with less accuracy. Some gulfs and inland seas appear to deviate in some measure from the general rule. This is more particularly the case where the communication of such seas with the ocean is narrow; and there are a few other exceptions.* When the general motion of the ocean or of the trade-winds is directed into the mouth of an inland sea, it has a tendency to raise its level above that of the ocean. On this account it is that the Arabian Gulf or Red Sea is higher than the ocean, and still higher than the Mediterranean, which, from the opposite action of the wind and the great evapor-

* Strabo says the level of the Gulf of Corinth is higher than that of the Gulf of Cenchreæ.

ation, is supposed to be a little below the general level.* Some gulfs and inland seas, as the Baltic and Black Sea, rise in spring, from the copious influx of river water, and are lowered in summer by evaporation and the efflux at their mouths. Of late years, there has been considerable discussion regarding the subsidence of the Baltic below the level it had formerly maintained. Whilst some support this opinion, and venture to explain the cause of the subsidence, others deny the fact altogether. The trade-winds and general westward motion of the ocean force in the water into the Gulf of Florida, so as to maintain a higher level there than on the western coast of the Isthmus of Darien.† The consequence of this accumulation of water is, that it generates a current moving northwards; and which, after various windings through the Atlantic, at length reaches the western shores of Europe, as will be more particularly noticed hereafter. Some naturalists allege, that the *débris*, or alluvial matters daily abraded by the action of the weather on the surface of the land, and swept into the ocean by the rain and rivers, must, at length, raise the level of the ocean till it cover the whole globe, and restore the reign of ancient chaos. Unless there be some compensating process, which either makes up for the exhausted materials, or gradually elevates the entire continents above the water, it is not very easy to guess at an alternative. A compensating power is situated deep in the crust of the earth.

840. *The taste of sea water* is disagreeable and bitter, at least when taken from the surface or near the shore; but when drawn from great depths, its taste is only saline. It would therefore seem that the bitterness is owing to the greater abundance of animal and vegetable matter near the surface. Man, in a civilised state, cannot make use of sea water as drink; yet it is said that the inhabitants of the Isle of Paques, in the Pacific Ocean, make it their usual beverage. Some of the lower animals occasionally travel far to drink sea water; Sheep are very fond of licking the dry salt; and so are many horses and cattle. With them it is a cure for various complaints. Several attempts have been made to render sea water potable, or to free it from salt. Distillation is the most effectual; but the expense of fuel is a serious objection to this method at sea, and, after all, it does not divest it of all its bitterness. Thus, in the midst of water, mariners are frequently in danger of dying of thirst, when they run short of fresh water. Sea ice, when melted, affords nearly fresh water; but being devoid of air, its taste is not very agreeable, though it would be highly prized in time of need. A temporary, and in some degree an imaginary, relief may be obtained, by holding salt water in the mouth.

841. *The saline contents of the waters of the wide ocean* do not, so far as experience has gone, differ much in different latitudes and under different meridians, although we ought to find the sea fresher in the spaces occupied by the internal limits of the trade-wind, and also in those tracts of the ocean where calms and a high temperature prevail, as on the west coast of Africa. The mean is about 3·5 per cent. in the weight of the water; but the saltiness is more or less affected by currents and storms. It is diminished at the surface during heavy rains, and by the discharge of rivers; but increased by evaporation, which carries off the water fresh, and leaves the salt behind: hence there is often little consistency in detached observations. From a great variety of experiments, Dr. Marcet concludes: 1. That the Southern Ocean contains more salt than the Northern, in the ratio of 1·0291 to 1·02757. 2. That the mean specific gravity of sea water near the equator is 1·02777, intermediate between those of the northern and southern hemispheres. 3. That there is no notable difference in sea water under different meridians. 4. That there is no satisfactory evidence that the sea at great depths is more salt than at the surface. 5. That the sea, in general, contains more salt where it is deepest and most remote from land; and that its saltiness is always diminished in the vicinity of large masses of ice. 6. That small inland seas, though communicating with the ocean, are much less salt than the open ocean. 7. That the Mediterranean contains rather larger proportions of salt than the ocean. This last is explained from the fact, that a pretty strong current from the Atlantic always flows inward at the mouth of the Mediterranean, to supply, as was supposed, the water which escaped by evaporation, and left its salt behind. So great, however, is the influx, that this inland sea ought to have become perfect brine, or perhaps to have deposited beds of salt, if there were *no efflux*; and accordingly it is maintained that there is an outward current at the bottom, very deep, which carries off this excess of salt, and prevents its deposition in the vast hollows in the bottom. The water drawn up from this lower current is salter, in a small degree, than at the surface.

842. *The following are the mean specific gravities of the waters of different seas, according to Dr. Marcet's experiments:—*

Arctic Ocean	-	-	-	1·02664	Black Sea	-	-	-	1·01418
Northern Hemisphere	-	-	-	1·02829	White Sea	-	-	-	1·01901
Southern Hemisphere	-	-	-	1·02882	Baltic	-	-	-	1·01523
Yellow Sea	-	-	-	1·02291	Lake Ourmia, in Persia,	-	-	-	1·16507
Mediterranean	-	-	-	1·02930	Dead Sea	-	-	-	1·11100
Sea of Marmora	-	-	-	1·01915					

* *Vide* Maclaren on the level of the Red Sea, in the Edinburgh Philosophical Journal.

† The mean height of the Pacific above the Atlantic is said to be 3·52 feet.

843. *The saltness of inland seas* is subject to many varieties. In the entrance to the Black Sea, the water is much saltier at the bottom than the surface. To account for this, it is said that an under current enters from the Mediterranean. It is well known that there is an outward current at the surface, which brings with it the less salt water of the Black Sea. The saltness of inland seas is often affected by the direction and strength of the wind, either forcing in, or retarding the entrance of, water from the ocean. Accordingly, from the experiments of Wilcke, it appears that the saltness of the Baltic is increased by a west wind, and still more so by a north-west wind; but it undergoes a diminution when the wind is from the east. Thus, the specific gravities are, for a

Wind at W.	-	-	-	-	1.0067	Storm at W.	-	-	-	-	1.0118
Ditto at N. W.	-	-	-	-	1.0098	Wind at E.	-	-	-	-	1.0039

Hence, the proportion of salt in the Baltic depends in no small degree on the different winds; a proof that the salt is not only derived from the neighbouring ocean, but that storms have a much greater effect on it than has been commonly supposed.

844. *The constituent parts of sea water* have been an object of examination to many chemists, and various sets of experiments made to determine them. The late Dr. Murray of Edinburgh was of opinion that there were various sources of fallacy in analysing sea water; and that different modes of operating on the same water gave very different results. Two reasons are assigned for this; viz. that some of the different salts mutually decompose each other in the process, and that a part is lost altogether by evaporation, especially if the temperature be high. According to this eminent chemist, 10,000 parts of water from the Firth of Forth, which is not sensibly different from that of the ocean, contain 220 parts of common salt, 33 of sulphate of soda, 42 of muriate of magnesia, and 8 of muriate of lime. On analysing sea water from N. latitude $25^{\circ} 30'$, W. longitude $32^{\circ} 30'$, Dr. Marcet made the numbers respectively 266, 47, 52, and 12. According to Bladh, the saltness is greater about the tropics than at the equator. Dr. Trail maintains the contrary; and also that the saltness increases with the depth.

845. *Ice is formed on the sea*, though its saltness enables it to resist the process of congelation at the ordinary freezing point of fresh water. This quality does not withstand the rigour of the Arctic regions, where the temperature of the air has been observed so low as 55° F. Sea water freezes about 28° , but the temperature varies a little with the saltness.—It is a curious circumstance, that sea water parts with its salt in freezing.* Hence compact transparent sea ice affords fresh water on being melted. When, however, the ice is of a loose or cellular texture, its pores sometimes contain liquid brine; and therefore, on being melted, it affords brackish water. It is supposed to be the affinity between the water and salt which retards the congelation of sea water; because the greater the saltness, the lower is the freezing temperature. Detached masses of ice are occasionally met with, floating in the ocean at so low a parallel of latitude as 40° in both hemispheres; having been conveyed thither by currents from the polar regions.† At the parallel of 50° they are more abundant; and there it is common, in winter, to see the shallow edges of the sea covered with ice. At 60° N. latitude, the gulfs and inland seas are frequently frozen over their whole surface. As we proceed toward the poles, the ice becomes more and more abundant, and of larger dimensions, till at length we come to *fields* of ice, and *icebergs* or mountains of ice. The process of congelation commences at the surface of the sea, with the formation of slender prismatic crystals resembling wet snow: this the seamen call *sludge*. The surface is at first rough; but, by the union of the crystals and the accumulation of the *sludge*, the surface becomes smooth and forms a continued sheet, which is next broken, by the agitation of the water, into fragments of about three inches diameter; these again coalesce into a continued sheet of a stronger texture, which is in its turn broken as before, but into larger fragments called *pancake ice*. Where the water is free from all agitation, the congelation goes on more regularly, and some allege more rapidly. During 24 hours of keen frost, the ice frequently attains a thickness of from two to three inches, and is soon fit for walking on: it is then called *bay ice*. When the thickness is about a foot, it is called *light ice*; and when three feet thick, *heavy ice*. The term *field* is given to a sheet of ice so extensive that its farther end cannot be seen from a mast-head. Very large loosened pieces, whose boundaries may be seen readily, are called *floes*. Fragments of thick ice floating together are called *brash ice*. Floating ice of any sort, sufficiently loose to allow a vessel to pass through, is called *open* or *drift ice*. Indeed, there is no end to the terms which seamen apply to different sorts of ice. The sudden disruption of extensive fields is sometimes produced by that powerful tendency to undulation of the surface, communicated by the motions of the adjoining liquid surface of the ocean during a continued storm, which is denominated a *ground swell*. The ice, when thin, merely yields; but, if thick and little flexible, it is broken with tremendous noise. A

* Although some have assumed 28° Fahrenheit, which is the melting point of sea ice, as the mean temperature of the pole, it is evident from the observations of Parry, Scoresby, and others, that it is about zero of Fahrenheit's scale.

† Horsburgh mentions icebergs having been met with in South lat. $35^{\circ} 54'$, and East long. $17^{\circ} 59'$.—*Phil. Mag.*

very interesting account of such a phenomenon is given by a party of missionaries who passed along the coast of Labrador in sledges drawn by dogs. They narrowly escaped destruction; but were near enough to witness all its grandeur. "The missionaries met a sledge with Esquimaux turning in from the sea, who threw out some hints that it might be as well for them to return. After some time, their own Esquimaux hinted that there was a ground swell under the ice. It was then scarcely perceptible, except on lying down and applying the ear close to the ice, when a hollow disagreeable grating noise was heard ascending from the abyss. As the motion of the sea under the ice had grown more perceptible, they became alarmed, and began to think it prudent to keep close to the shore. The ice also had fissures in many places, some of which formed chasms of one or two feet; but as these are not uncommon even in its best state, and the dogs easily leap over them, they are frightful only to strangers. As the wind rose to a storm, the swell had now increased so much that its effects on the ice were extraordinary, and really alarming. The sledges, instead of gliding smoothly along as on an even surface, sometimes ran with violence after the dogs, and sometimes seemed with difficulty to ascend a rising hill. Noises, too, were now distinctly heard in many directions, like the report of cannon, from the bursting of the ice at a distance. Alarmed by these frightful phenomena, our travellers drove with all haste towards the shore; and as they approached it, the prospect before them was tremendous. The ice, having burst loose from the rocks, was tossed to and fro, and broken in a thousand pieces against the precipices with a dreadful noise; which, added to the raging of the sea, the roaring of the wind, and the driving of the snow, so completely overpowered them as almost to deprive them of the use both of their eyes and ears. To make the land was now the only resource that remained; but it was with the utmost difficulty that the frightened dogs could be driven forward; and as the whole body of the ice frequently sunk below the summits of the rocks, and then rose above them, the only time for landing was the moment it gained the level of the coast, — a circumstance which rendered the attempt extremely nice and hazardous. Both sledges, however, succeeded in gaining the shore, and were drawn up on the beach, though not without great difficulty. Scarcely had they reached it, when that part of the ice from which they had just escaped burst asunder, and the water, rushing up from beneath, instantly precipitated it into the ocean. In a moment, as if by signal, the whole mass of ice for several miles along the coast, and extending as far as the eye could reach, began to break and to be overwhelmed with the waves. The spectacle was awfully grand. The immense fields of ice rising out of the ocean, clashing against one another, and then plunging into the deep with a violence which no language can describe, and a noise like the discharge of a thousand cannon, was a sight which must have struck the most unreflecting mind with solemn awe. The brethren were overwhelmed with amazement at their miraculous escape; and even the pagan Esquimaux expressed gratitude to God for their deliverance."*

846. *The term iceberg* is applied to huge masses of ice resembling mountains, whether resting on the land or floating on the sea. The latter sort appear to be sometimes formed in the sea itself, by the accumulation of ice and snow; at other times to be fragments of land icebergs or glaciers, which have been piling up on shore till quite overgrown, and ultimately broken and launched into the ocean by their own weight. Masses of this sort abound in Baffin's Bay, where they are sometimes two miles long, and half or one third as broad. They are bristled with various spires, rising, perhaps, 100 feet above the surface, and descending half as much below it. When compact ice floats in water, the part under the surface is about nine times as great as that above it; and hence the icebergs may sometimes descend to a great depth, though they should be far from consisting of very compact ice. Icebergs of an even surface, rising 90 feet above the sea, and having an area of five or six square miles, are very common. Those of East Greenland are of inferior size, and they are still smaller around Spitzbergen, where some of enormous dimensions occur on shore. The reason which Mr. Scoresby assigns for this is, that, owing to the shallowness of the water into which the huge fragments are precipitated, they are all shattered against the bottom into a thousand pieces before they are fairly launched into deep water. "On an excursion to one of the Seven Icebergs, in July 1818," says Mr. Scoresby, "I was particularly fortunate in witnessing one of the grandest effects which these polar glaciers ever present. A strong north-westerly swell, having for some hours been beating on the shore, had loosened a number of fragments attached to the iceberg, and various heaps of broken ice denoted recent shoots of the seaward edge. As we rowed towards it, with a view of proceeding close to its base, I observed a few little pieces fall from the top; and while my eye was fixed upon the place, an immense column, probably 50 feet square and 150 feet high, began to leave the parent ice at the top; and leaning majestically forward, with an accelerated velocity fell with an awful crash into the sea. The water into which it plunged was converted into an appearance of vapour or smoke, like that from a furious cannonading. The noise was equal to that of thunder, which it nearly resembled. The column which fell was nearly square, and in magnitude resembled a church. It broke into a thousand pieces. This cir-

* Brown's History of the Propagation of Christianity, vol. ii. p. 57

cumstance was a happy caution; for we might have inadvertently gone to the very base of the icy cliff, from which masses of considerable magnitude were continually falling." In 1619, a huge mass of this sort fell on a Russian ship. It broke the fore and main masts, sprung the bowsprit, and flung the ship over with such violence that a piece of ordnance was thrown overboard from under the half-deck, and the captain and some of the crew were projected in the same manner. The captain, however, escaped unhurt; but the mate and two others were killed, and many were wounded.

847. *Icebergs variously affect navigation.* They are often highly useful, by protecting navigators from gales, as well as from the concussions of drift ice, which moves more quickly when acted on by the wind than the massy iceberg. To the latter, ships are sometimes moored, but not without danger; for these floating masses are sometimes so nicely balanced as to be easily overturned, should they happen to catch the bottom of the sea. The concussion produced in this way sometimes detaches large fragments; and sometimes the iceberg rolls forward, to the imminent danger of the vessel, though perhaps 100 yards distant, — so great are the waves and whirls caused by such an occurrence. Many dangers and discouragements attend the navigation of the polar seas: but the recent attempts to discover a north-west passage through the Arctic Sea have rendered the ice a subject of considerable interest. These attempts have not yet been crowned with success: but different navigators have brought such different accounts of the state of the ice, that it is probably very changeable, and very difficult to examine. It is not quite agreed that any navigator has been within 6° of the North Pole; although some accounts pretend to a still nearer approach. Captain Parry, in his last voyage, reached to $82^{\circ} 45'$ N. lat. The failure of Captain Cook's attempt to penetrate to the South Pole gave rise to an idea, which has been pretty generally entertained since his time, that the South Pole is surrounded with fixed ice to the distance of 18° or 19° ; and a more recent Russian expedition gave still worse hopes, as they could not get beyond the latitude of 70° S. Mr. Weddell, however, has since reached 255 miles nearer the pole, and met with no such obstruction: this enterprising navigator contends strenuously that the South Pole must be free from ice, and might be reached by sea. Some of his arguments are rather plausible; but the question is involved in so many uncertainties, that nothing less than actual trial can decide it.

848. *The expansion and contraction of ice has important effects.* Though water undergoes a great expansion in the act of freezing, yet ice obeys the ordinary law of solids, — that of expanding by heat and contracting by cold. The effect, therefore, of intense cold is to contract ice, which, if of large dimensions, or fixed all around, has no alternative but to rend where it is contracting most. This is often attended with a tremendous report. On the contrary, a rise of temperature may not only bring the parts to meet again, but often makes them lap over, or burst up with great violence.*

849. *The motion of the waters of the ocean is almost perpetual; and it is believed, that without this provision in the economy of nature, the sea, in place of tempering and purifying the air, would both become putrid and exhale noxious vapours.*

850. *Waves.* The motions which first present themselves to our notice are the partial and alternate rising and falling of the surface, known by the name of undulations or *waves*. This sort of motion is caused by the wind, which, by dislodging or depressing a certain portion of the waters, has destroyed the equilibrium or level, which they naturally endeavour to recover. Waves may be compared to the reciprocations of water in a syphon or bent tube. It was in this way that Newton deduced the velocity of waves, and the time required to an undulation. If water ascend and descend alternately in the legs of a bent tube, and a pendulum be constructed whose length between the point of suspension and centre of oscillation is equal to half the length of the water in the tube, then this fluid will ascend and descend during each oscillation of the pendulum. Hence the velocity of waves is as the square roots of their breadths; the breadth being the distance between the tops of the ridges. In the same way, it may be shown that the apparent progressive motions of waves through spaces equal to their breadths are performed in the times in which pendulums oscillate whose lengths are equal to these breadths. Hence waves, whose breadth is $39\frac{1}{2}$ inches, will seem to pass over that space in one second. Waves are scarcely ever without progressive motion; but the real progress of the surface of the water is generally small, compared to the apparent motion of the waves; as is easily proved from any floating body which does not rise above the surface so as to be hurried forward by the wind. Waves are distinguished into natural and accidental. The natural are proportional to the strength of the wind producing them: — the accidental are occasioned by repercussion of the wind from hills and bold coasts, and by the dashing of the waves on rocks and shoals. Divers, it is said, find the water perfectly still at the depth of thirty yards, during the greatest tempest. But this can only be known of some sheltered spots; for when do divers descend in an open sea during a tempest? Waves are always seen rolling towards the shore; but an obstacle opposed to them becomes the centre of a new series which spreads in circles. One set of waves, however, may not interfere with

* The most satisfactory account of the polar ice is that of Scoresby, first published in the Memoirs of the Wernerian Natural History Society.

the motion of another, and they may mutually cross without interruption. Sometimes the ordinary oscillations are combined with a distant swell, called the *bore*, which rises impetuous after certain intervals. Breakers, or waves which break against some obstacle, when formed over a great extent of shore, are distinguished by the name of *surf*. The surf is greatest in those parts of the ocean where the wind blows always nearly in the same direction.

851. *Currents*. There are two permanent and general sorts of currents in the ocean, which are supposed to originate in two great movements, — that of the tropical waters westward round the globe, and that of the polar waters towards the equator. But it is plain that the latter, or polar currents, imply the existence of a *third* set, moving in the opposite direction; otherwise the waters at the poles would soon be exhausted, together with the ice from which they are partly derived. It is well known that the rain, fog, or snow, which fall in the polar regions, could never supply any perceptible current towards the equator. The movement of the tropical waters westward is ascribed to the agency of the trade winds, which, blowing constantly from the east, must impress their motion on the sea to a certain extent. But the resulting current is necessarily modified by the position of the great continents. This grand westerly motion prevails generally between 30° S. and 30° N. latitude. According to Humboldt, its mean velocity is from nine to ten miles a-day. In the Atlantic it separates into two branches, one of which forms the well known Gulf Stream. This branch flows northward, through the middle of the Atlantic, till it reaches the Cape Verd Islands: it then turns west, passes through the Caribbean Sea, and the strait between Cuba and Yucatan, winds round the Mexican Gulf, and rushes out by the Bahama Channel; then spreading out to a greater breadth, it sweeps along the shores of the United States to Newfoundland. At this point it is deflected south-eastward by a southerly current from Baffin's Bay, and passing the Azores and Canary Isles, returns in a great measure into itself, and repeats its circumgyration. The waters of the North Atlantic, between the latitudes of 11° and 43° , thus form a continued whirlpool, completing a circuit of 3800 leagues in about 34 months. Its velocity is greater as the depth and breadth are less. Its breadth is 51 leagues in the Bahama Channel, and velocity from three to five miles an hour. In its retrograde course from longitude 50° to the Azores the breadth is 160 leagues, and velocity from seven to eight miles a-day. An insulated expanse of almost motionless water, 140 leagues in breadth, occupies the interior of the circuit. This grand current sends off one branch near Newfoundland, which proceeds north-eastward, and sometimes deposits tropical fruits on the shores of the British isles and Norway. In 1776, Dr. Franklin traced this current, by means of its high temperature, quite across the Atlantic; and, since his time, it has been more closely traced, especially by Captain Sabine. A second branch, escaping at the Azores, enters the Straits of Gibraltar, and forms the upper and middle current which prevails in that strait. Another branch of the great tropical current sets along the coast of Brazil, and at length passes through the Straits of Magellan. In the Pacific Ocean the waters have a general westward motion from the coast of Peru, which must be partly supplied by the last-mentioned current after doubling Cape Horn. The current from the coast of Peru is less perceptible, till it enters the Indian Ocean; when, strengthened by the northerly currents there, it flows along the eastern coast of Africa, and doubles the Cape of Good Hope, in a rapid stream, 130 miles broad, and from 7° to 8° warmer than the contiguous sea. A current from the South Pole sets along the west side of New Holland into the Bay of Bengal: it is supposed that other portions of the general polar current deflect the great westerly current northward, after it has passed the southern promontories of Africa and America. In the Northern Ocean, in the space comprised between Greenland and the coasts of Britain and Norway, and between Labrador and Spitzbergen, a great body of waters, acted on by three or four lateral currents, is supposed to perform a perpetual circuit. These waters receive their impulse eastward from a branch of the Gulf Stream, which passes from Newfoundland along the north-west coasts of Scotland and Norway. At the North Cape in Lapland, a great westerly current from Nova Zembla turns the waters north-westward along both sides of Spitzbergen. Beyond this island, being met by a current from the pole, they turn south-westward, and pass along the coast of Greenland to Davis's Straits, where they are deflected southward by a fourth current from Baffin's Bay; and having returned to Newfoundland, recommence their revolution. Thus two great whirlpools, connected with one another, touch at the Bank of Newfoundland, which seems to be a bar cast up by their conflicting waters; and revolving in opposite directions, occupy four fifths of the North Atlantic. The small current which sets from the Bay of Biscay across the mouth of the English Channel, and through St. George's Channel, is most probably a branch of the Gulf Stream which had come off at the Azores. Were other parts of the ocean as minutely examined as the North Atlantic, it is to be expected that other great vortices would be discovered.

852. *Local or temporary currents* are produced by winds, the discharge of rivers, the melting of ice, &c. In general, currents which do not descend to a great depth are liable to change with the winds, particularly when they blow for a long time with equal force, as the mon-

soons do. These winds give by turns entirely opposite directions to the currents which prevail from the Maldivia Islands to Arabia and Zanguebar. When the supply of fresh water in an inland sea falls short of what is carried off by evaporation, its level will have a tendency to fall below that of the ocean; and hence the water will flow into it from the ocean. But, as formerly noticed, a continual influx of salt water, to be concentrated by evaporation, must have a tendency to render such inland sea salter than the ocean; and the salter water being the heavier, naturally endeavours to keep under the lighter, which enters from the ocean. In this way, it forms an outward current in the bottom of the entrance. Such is said to be the case with the Mediterranean, as was first hinted by Dr. Hudson in 1724. The reverse of all this takes place where the supply of fresh water in an inland sea exceeds the evaporation, as is the case with the Baltic, the Black Sea, and the Sea of Asoph. In these the outward fresher current is uppermost, while the heavier salter current enters below. Since the mean quantity of salt brought in must equal what is carried out, if no permanent change take place in the saltiness of the inland sea, it follows that the salter current is the smaller of the two. However, the weather sometimes produces temporary exceptions to this general rule. The current which flows into the Mediterranean by the Straits of Gibraltar sets along the shores of Africa and Egypt to Syria, where it turns north-westward; and, joined by the current from the Dardanelles, it makes the circuit of the Adriatic, then of the coasts of Tuscany, France, and Spain, and ultimately returns to the Straits. In the Cattegat, a northern current proceeds from the Baltic along the coasts of Sweden; and another, a southern current, enters into the Baltic along the coasts of Jutland. In the German Sea, a north current sets from the Straits of Dover along the continental shore, while a south current comes from the Orkneys along the British coast.

853. *Whirlpools or eddies* are produced by the meeting of currents which come in different directions. These, by encountering in a narrow passage, turn, as it were, about a centre, which is sometimes spiral, till they unite or one of them escapes. The most celebrated whirlpools are the Euripus near the coast of Negropont, the Charybdis in the Straits of Sicily, and the Malstroem on the northern coast of Norway. Such eddies sometimes augment their force by means of two contrary high tides, or by the action of the winds. In certain states of the tide some of them cease altogether; but they do not fail to make up for this afterwards. Their danger to navigation is well known; but is, perhaps, inferior to the dread which they inspire. They draw vessels along, and dash them against the rocks, or engulf them in the eddies. The wrecks, perhaps, do not appear till some time afterwards; or, indeed, they may never be heard of at all. This has given rise to the notion that they have no bottom. The phenomena and dread of whirlpools have afforded excellent matter for marvellous fables both to the ancient poets and more modern writers.

854. *The tides* form a remarkable phenomenon, consisting in the alternate rise and fall of the surface of the sea twice in the course of a lunar day, or at a mean rate every 12 h. 25 m. and 14 s. The instant of low water is nearly, but not exactly, in the middle of the interval between two high waters. The tide generally takes nine or ten minutes longer in ebbing than flowing. At the new and full moon the tides attain the greatest height, and the interval between two high waters is least, viz. 12 h. 19 m. 28 s. At the quarters of the moon the tides are the least, and the interval the greatest, viz. 12 h. 30 m. 7 s. The time of high water is mostly regulated by the moon; and in general, in the open sea, is from two to three hours after that planet passes the meridian, either above or under the horizon. On the shores of large continents, and where there are shallows and obstructions, great irregularities take place in this respect; and when these exceed six hours, it may seem as if the high water preceded the moon's passage over the meridian. Though the tides seem to be regulated chiefly by the moon, they appear also in a certain degree to be under the influence of the sun. Thus, at the syzgies, when the sun and moon come to the meridian together, the tides, every thing else considered, are the highest. At the quarters, when the sun and moon are 90° distant, the tides are least. The former are called the *spring*, the latter the *neap* tides. The highest of the spring tides is not that immediately after the new or full moon; but is in general the third, and in some cases the fourth. The lowest of the neap tides occurs much about the same time after the quarters. The total magnitude of the tide is estimated by the difference between the heights of high and low water. The higher the flood tide rises, the lower the ebb tide generally sinks on the same day. At Brest, the medium spring tide is about 19 feet, and the mean neap tide about 9. On other parts of the coast of France opposite to England, the waters, being confined, rise to a great height, and do so on both sides of the Channel. At St. Malo it is from 45 to 50 feet. Still higher tides are said to occur at Annapolis Royal, in Nova Scotia; though there is something extraordinary in their being alleged to exceed 100 feet. It is the obstruction which the land presents to the motions of the waters which occasions tides of any consequence at all: were the globe entirely covered with water, the tides would be very insignificant. Thus, in the Pacific Ocean, the spring tide amounts only to 5 feet, and the neap from 2 to 2.5 feet. On the other hand, a free communication with the ocean is indispensable, to produce

a high tide. Thus, in inland seas, the tides are very trifling, because the luminaries act nearly equally over the whole surface at the same time.

855. *The height of the tide* increases as the sun or moon is nearer the earth, but in a higher ratio. The rise of the tides is likewise greater when the sun or moon is in the equator, and less as they decline from it. When the observer and the moon are on the same side of the equator, the tide which happens when the moon is above the horizon is greater than when she is below it. The reverse occurs when the observer and the moon are on opposite sides of the equator. If the tides be considered relatively to the whole globe and to the open sea, it appears that there is a meridian about 30° eastward of the moon, where it is always high water, both in the hemisphere where the moon is and in the opposite. On the west side of this circle the tide is flowing; on the east it is ebbing; and on the meridian, which is at right angles to the same, it is every where low water. These meridian circles move westward, keeping nearly at the same distance from the moon: only approaching nearer to her when new or full, and withdrawing at the quarters. In high latitudes the tides are very inconsiderable. It is probable that at the poles there are no diurnal tides; but there is some ground for thinking that the water will rise higher at the pole to which the luminaries are at any time nearest, than at the opposite.

856. *The great wave* which follows the moon as above described, and constitutes the tide, is to be considered as an undulation or reciprocation of the waters of the ocean; in which there is, except when it passes over shallows or approaches the shore, very little progressive motion. In all this we are as yet overlooking the operation of local causes, winds, currents, &c., by which these general laws are modified, over-ruled, or even reversed. Most people find little difficulty in conceiving how the waters should rise on the side of the globe which is next the moon; but there can scarcely be a harder task than bringing many to see *why the waters should at the same time rise on the side which is turned from the moon*. We must, however, confine ourselves to a very brief and palpable explanation. The force by which the moon draws any particle of our globe towards her is greater when it is nearer to her and less when more remote. The force, therefore, with which the moon attracts the particles on the side nearest her is greater than the average force which she exerts on the whole globe. These particles, therefore, rise or endeavour to come near the moon. On the other hand, the force by which the moon draws the particles which are farthest from her being less than the average force, these particles endeavour to recede from the moon, and in so doing they also recede from the earth's centre; that is, they rise higher than the general level. The action of the sun is similar to that of the moon; but his being almost four hundred times as distant greatly diminishes his effect. At the new and full moon the luminaries act together, and produce *spring* tides. The highest of all are a little after the autumnal, and before the vernal, equinox; and the least spring tides occur a little after the solstices. At the quarters of the moon her action is opposed by that of the sun, and therefore *neap* tides are the result.

857. *The time of high water* deserves consideration. The preceding is sufficient to show that the phenomena of the tides are effects that might be expected from the principle of attraction or gravitation; but since the waters necessarily occupy some time in moving from one place to another, this is the reason why the high water occurs, not when the moon is on the meridian, but from two to three hours afterwards. For the same reason, when the sun is before or west of the moon, he hastens the rise of the tide; and when behind her, he retards it. Considerable extent of surface is necessary, in order that the sea should be sensibly affected by the action of the sun and moon; for it is only by the inequality of such action on different parts of the mass of waters that their level is disturbed. In narrow seas, and on shores far from the main body of the water, the tides are not caused by the direct action of the sun and moon, but are waves propagated from the great diurnal undulation. Of this the tides on the coast of Britain and in the German Sea are remarkable examples. The high water transmitted from the tide in the Atlantic reaches Ushant between three and four hours after the moon has passed the meridian, and its ridge stretches north-west, so as to fall a little south of the coast of Ireland. This wave soon after divides itself into three branches; one passing up the British Channel, another ranging along the west side of Ireland and Scotland, and the third entering the Irish Channel. The first of these flows at the rate of about 50 miles an hour, so as to pass through the Straits of Dover, and to reach the Nore about midnight at the time of spring tide. The second, being in a more open sea, moves more rapidly, reaching the north of Ireland by six p. m.; about nine it has got to the Orkneys, and forms a wave or ridge stretching due north; at twelve, the summit of the same wave extends from the coast of Buchan eastward to the Naze of Norway; and in twelve hours more it passes southward through the German Sea and reaches the Nore, where it meets the morning tide that left the mouth of the Channel only eight hours before. Thus, these two tides travel round Britain in 28 hours; in which time the primitive tide has gone quite round the globe, and nearly 45 degrees more. Various curious anomalies are observed in the tides of particular places: such as their ceasing altogether for a day or two, at a certain age of the moon; while at other times they become considerable, though perhaps occurring

only once a-day. It is said that on some coasts there is never more than one tide in the course of a lunar day, which is probably owing to some oversight: but it may be shown from theory, that if the observer's distance from the pole be equal to the moon's declination, he will see but one tide in the day. Small tides occur six times a-day on the shore of the Isle of Negropont.*

858. *The agency of the tides is probably very extensive* in many of the operations of nature, and in particular in those which regard geology. The late Professor Robison suggested how experiments might be made to determine the mean density of the globe, from the temporary change which is undoubtedly caused on the direction of gravity by the great body of water brought to Annapolis Royal, and then withdrawn by the stream tides.

SECT. II. *Springs.*†

859. *Springs* are composed of the waters issuing from crevices in the earth. Of such there are great varieties. Some of the principal distinctions, independently of the qualities of their waters, are, — *temporary* springs, which only flow during a certain season of the year; *perennial*, which always run; *intermitting*, which alternately run and cease, either wholly or in part, at short intervals; *periodical*, which flow and ebb regularly at particular periods; *spouting*, which issue with considerable force, forming, perhaps, a jet of water. The magnitude of springs passes through every gradation, from being scarcely perceptible, to considerable rivulets. They have, likewise, a wide range of temperature; but necessarily limited between the freezing and boiling points. It is most usual for springs which are large, and which appear to issue from a considerable depth, to have nearly the mean temperature of the place; and in some instances the temperature is remarkably steady, — not the slightest variation being perceptible in the course of the year. Hence apparently, or relatively to the air, they are colder in summer and hotter in winter. It is, no doubt, this contrast which has given rise to the popular notion, that good springs are really colder in summer and hotter in winter. Nothing is more common than to see a well smoking during intense frost, which shows nothing of the kind during warm weather; but it does not require a really high temperature to exhibit such an appearance, but only a temperature not so low as that of the air. The most that any spring keeps within the range of both seasons, is to remain always at one temperature. The greater number of the smaller springs, however, become a little warmer in summer and colder in winter; particularly those which come along for a considerable way at a small depth under ground. By so doing, they participate in the temperature of the surface, which varies with the season: but all springs preserve a greater warmth than the mean temperature of winter; and, excepting the thermal or hot springs, they do not reach the mean heat of summer.

860. *Hot springs* are those which preserve a heat above the mean temperature of the place. Such as are merely tepid are common in most countries, especially in mines. Those having a considerably higher temperature are less frequently met with, and mostly in volcanic districts; but some of them reach the boiling point, or are actually boiling and spouting forth with great violence, which indicates their having had a still higher temperature before getting vent. The most remarkable are the hot springs of Iceland, some of which are considered among the greatest wonders of the world. They are believed to be more abundant in Iceland than in any other country. But the interest which the number and variety of these hot springs excites in a person who never saw any thing similar, is quickly lost in the feelings which are roused on beholding the magnificent and tremendous explosions of the Geysers, as they are called. Besides the principal fountains, there is a great number of boiling springs, cavities full of hot water, and several from which steam issues. There are also some places full of boiling mud of grey and red colours. The silicious depositions of the waters of the Great Geyser have formed for it a basin 56 feet in diameter in one direction, and 46 in the other; a projection from one side causing it to deviate from the perfect circle. In the centre of this basin is a cylindrical pit or shaft 10 feet in diameter. Through this the hot water rises gradually, filling it and the basin, after which it runs over in small quantities. At intervals of some hours, when the basin is full, explosions are heard from below, like the report of distant cannon, and at the same time a tremulous motion of the ground is felt all around the basin: immediately the water rises in a mass from the pit, and sinking again, causes the water in the basin to be agitated and to overflow: another and a stronger propulsion follows, and clouds of vapour ascend. At length, strong explosions take place, and, large quantities of steam escaping, the water is thrown to a height of from 30 to 90 feet, and even to 200 or 300 feet. The steam, coming into contact with the cold air of that climate, is condensed into thick clouds, which are tossed and rolled with great rapidity; the whole forming a very singular and magnificent exhibition. After continuing for some time, the explosions cease, when the basin and pit are found empty. Bursts of steam sometimes take place, when the water is rising, without any warning by subterranean

* *Vide* Stevenson's great work on the Bell Rock Light-house, for observations on Tides in the British seas.

† We are much in want of a natural and chemical history of springs. We shall soon, either ourselves or by means of one of our pupils, lay before the public a treatise on this important subject.

noise. These phenomena seem to be occasioned by steam finding its way from below into cavities, where part of it is condensed into water, which water is at length forced out by the action of the steam under high pressure. The New Geyser is somewhat smaller than the other. There are many hot springs of less note in Iceland; but perhaps the most curious of the whole is the Tunguhver. Among a great number of boiling springs are two cavities, within a yard of each other, from which the water spouts alternately: while from one the water is thrown about ten feet high in a narrow jet, the other cavity is full of water boiling violently. This jet continues about four minutes, and then subsides; when the water from the other immediately rises, in a thicker column, to the height of three or four feet. This continues about three minutes; when it sinks and the other rises, and so on alternately.

861. *The natural jets of water, called sprouting springs*, only differ from the rest in coming down some close canal from a fountain on a higher level. Being thus closely confined, they burst forth in consequence of the pressure, in the same manner as the artificial spouting fountains do.*

862. *Intermitting fountains* have sometimes been viewed by the multitude as of a miraculous nature. One at Como, in Italy, rises and falls every hour: another at Colmars, in Provence, rises eight times as often. At Fronzanches, in Languedoc, one has a period of 24 hours 15 minutes. England affords many examples of such springs; particularly those on the sea coast, whose waters rise and fall with the pressure of the tides. The town of Tideswell, in Derbyshire, is named from a noted fountain of this sort which once flowed there, but has now ceased to observe its tides. The principles on which intermitting springs depend are attempted to be explained in every popular treatise on hydrostatics and hydraulics.†

863. *Various have been the opinions of philosophers concerning the origin of springs*. Some suppose that sea water is conveyed through subterraneous ducts or canals to the places where the springs flow out of the earth: but in this way fresh-water springs could not be produced; because sea water cannot be freed from its salt by filtration. It is, besides, difficult to conceive how the water should filter *upwards*. In order to overcome these objections, recourse has been had to subterranean heat, by which the water is conceived to rise upwards in vapour through certain fissures and cavities of the mountains, where it is collected, and issues forth, as we see, in springs. Others vary the hypothesis a little, by saying that the sea water is raised through the mountains by capillary action: but here we ought still to have salt springs; and it has been further objected that a current cannot be produced by capillary action.

864. *The most probable theory is that proposed by Dr. Halley*, who maintained that springs are nothing more than a part of the water which falls on higher ground filtrating through, and afterwards issuing forth at a lower level. This, it is true, does not at first sight appear to account for the permanent flow of springs during dry weather. To complete the theory, it is supposed that the water at first collects in large subterranean cavities, from which it afterwards filtrates slowly, and passes towards the springs. The disposition of the rocks in strata contributes much to the collecting of the waters under the surface, and conveying them without waste, as if in close pipes, till they are united in fountains, lakes, rivers, &c. Dr. Halley showed that the evaporation from the sea alone is a sufficient supply for all the waters that the rivers carry into it. His calculation was founded on a very complex view of the subject, and liable to several objections. Buffon took a more simple view of the matter, by selecting one of those lakes that send out no stream to the ocean, and showing that the probable evaporation from the surface of the lake is equal to all the water carried into it.

865. *The theory of hot springs* is deserving of consideration. It has been ascertained that the greater number of warm and hot springs occur in volcanic countries — where volcanoes formerly burnt or are still in a state of activity; and of those that do not occur in volcanic districts, some are associated with trap and granite rocks to which most geologists assign an igneous origin. Hence it is inferred that they owe their temperature to the same cause or causes as gave rise to volcanic and ignigenous rocks. That the heat of such springs is often connected with volcanic action cannot admit of doubt; for, from the Geyser of Iceland, the transition is almost uninterrupted to the hot springs in the dormant volcano of the island of Ischia, and from thence to those connected with the processes which formerly took place in the now extinct volcanoes of Hungary and Auvergne. The hot and warm springs of Bath and Bristol, however, occur in a limestone country where no igneous rocks are visible; but these may be under the limestone. This opinion is further countenanced by the fact that many of the hot springs met with in primitive, and also in secondary, formations, occur in spots where the strata appear to have been disturbed by igneous agency. Of this there is a striking example at the hot springs of Carlsbad in Bohemia; the hot springs of

* Vide Ed. New Phil. Journal, vol. ix. for observations on spouting springs and Artesian wells.

† Vide Ed. New Phil. Journal, vol. viii. for an account of intermitting springs.

Clifton issue from a limestone which appears, at an early period, to have been disturbed by igneous action : the hot springs of Pfeffers, in the Grisons, gush from a ravine from 400 to 654 feet in depth, and so perpendicular that the provisions required for the inmates of the bath are lowered from ropes attached to the summit of the cliff, and so narrow that the rocks in some places touch overhead, and nowhere, perhaps, are more than 30 feet apart. The most obvious explanation of such a phenomenon is to be found in some convulsion of nature, such as that caused by an earthquake, or the sudden elevation of a large tract of country. The other hot springs in Switzerland appear in circumstances for the most part similar. Those of Weissenburg, in the canton of Berne, rise out of a gorge of the same kind as that of Pfeffers : those of Louechi appear at the foot of the mural precipice of the Gemmi ; whilst the spring of Baden, in the canton of Argovie, from which the only remaining one, that of Schinzath, is not far removed, lies near the point where, in consequence of the two mountains of Staffelegg and Lagern having been severed asunder by some great convulsion, the waters of the Rhine and of the other rivers, — which appear to have once constituted a single lake extending from Coire in the Grisons to this mountain ridge, including the lakes of Zurich and of Wallenstadt, with the intermediate country, — in one continuous sheet of water, flowed off by the channel now taken by one of the rivers, the Limmat alone. Thus the Rhine, says Dr. Daubeny, may be supposed to owe its original direction to the event which produced the hot spring, and its present course to that which occasioned another.

866. *Some springs apparently emit inflammable matter ;* for when a light is applied, it seems to take fire like ardent spirits. But it is not so much the water that is inflammable, as some gas which it exhales, or bituminous matter floating on its surface.

867. *Springs in the sea.* Powerful springs are occasionally met with boiling up in the bottom of the sea, so as, in some instances, to rise above the surface. From some of them navigators can draw up fresh water fit for taking on board as store. The natives, in certain places, know where to dive under the surface of the sea for fresh water ; which, perhaps, may be the only source whence they could obtain it.

868. *Mineral waters, and the quantity of matter they deposit.* Springs in their course through strata convey along with them portions of the strata, not only from higher to lower situations, but also from below upwards. They contain salts, earths, acids, metals, and inflammable matters, of very varied nature : the variety depending sometimes on the nature of the strata through which they pass ; at other times, as in those that rise upwards in volcanic districts, on igneous agency. Hoffmann remarks, that when warm and hot springs, and those richly impregnated with mineral matters, occur in countries at a distance from active and extinct volcanoes, we observe the strata from which they issue to be much deranged, thus intimating that formerly earthquakes and other igneous agencies were at work in the districts where these springs now flow. The quantity of mineral matter brought from the interior of the earth by springs is very great ; whether that matter is abstracted from the strata traversed by the springs, or is brought by them from a great depth, as in volcanic countries. Even some calcareous springs in Britain deposit annually vast quantities of calcareous tuffa and calcareous sinter. In the neighbourhood of Edinburgh there are great calcareous deposits from calcareous springs that flow through limestone rocks ; and appearances of the same description abound around all the calcareous springs in England. Near to Clermont, in France, some calcareous springs, rising through rocks of *granite and gneiss*, have formed a mound or hill 240 feet high. Many of the great edifices in Rome are built of calcareous deposits from calcareous springs. The hot springs of Carlsbad annually deposit much calcareous tuffa and sinter. Other springs, as the hot springs in Iceland and in the Azores, deposit annually great quantities of silica. Salt springs also bring from the interior of the earth, and spread over their vicinity, much salt, which salt may be derived from the saline clays and salt beds through which they pass ; in other instances the salt may come from a great depth as an igneous production.

869. *Chemical nature of spring waters.* The water of springs, when very pure, is named *soft* ; if impregnated with calcareous salts, *hard* ; and if impregnated with various mineral matters, *mineral*. It was long believed that hard water was unfit for brewing and distillation ; and hence soft water was often procured for these operations, at great expense ; but it is now found that water which owes its hardness to lime is the most proper of all for the fermentation of worts. A time will, however, be necessary to remove the popular prejudice in favour of soft water. We have, in the following Table, given a view of the composition of the most celebrated mineral springs.

870. *According to some chemists* the salts found by chemical analysis in springs are considered as existing in the waters ; the late Dr. Murray considers the compound existing before concentration of the water as, in all cases, the most soluble salts that can be formed out of the ingredients present. But, in reality, so far from our having determined in any given case the nature of the existing combinations between the ingredients, we are ignorant even of any method by which such knowledge is attainable. If, says Berzelius, the physician enquires of the chemist, what the proportion these salts bear to each other in any given case may be, the latter must reply, that this is a question as to which we are at present entirely

in the dark ; as the proportion depends not only on the quantity of the acids and bases present, which admits being ascertained, but also of the relative force of affinity subsisting between the one and the other, for determining which we have as yet no data whatever.

SECT. III. *Lakes.*

871. *A lake is a body of water which does not communicate with the ocean.* Independently of the qualities of their waters, lakes are distinguished into several sorts : — 1. Those which receive streams of water, and have an outlet, are the class of lakes best known. It is rare for a lake to give rise to more than one river, which often bears the name of the principal stream which flows into it, though these two rivers may differ materially in every respect. 2. Those which receive streams of water, and often great rivers, without having any visible outlet. This class is less numerous than the former, and is confined to warm climates ; but the largest of all lakes, the Caspian Sea, belongs to it. 3. Those which receive no running water, but have an outlet, — circumstances which imply that such lakes are fed with springs from beneath, or with small imperceptible streams from the adjacent land. 4. Those which receive no running water, and have no visible outlet. Lakes of this class, exclusive of marshes, are for the most part small, and merit little attention. Without regarding the foregoing distinctions, some writers subdivide lakes into two kinds, according to the general character of the surface in which their basins are situated : viz. those which are formed in deep hollows between the ridges or at the foot of mountains, and fed by springs or torrents ; and those which are formed in low and level countries for want of a general declivity, or dammed up by a mere accumulation of alluvial matter.

872. *Subterranean lakes form a class of lakes differing remarkably from all the preceding,* and are bodies of water contained in cavities quite covered over by earthy strata. It is only when such cavities are laid open by earthquakes, by the falling asunder of mountains, by the action of the weather or of rivers, by the operations of mining, or when the roof falls in, that their situation becomes known. But they are probably very numerous, though perhaps often of small size. It is not easy to account for the permanent and uniform flow of many springs on any other supposition. Some of them appear to give rise to rivers, while others are known to receive very considerable streams which lose themselves in the interior. Such are the numerous cavities of the Julian Alps. It is to similar reservoirs that we must attribute the periodical disappearance of certain lakes situated above ground. There are some caverns in Norway which afford a passage to rapid currents of water, as appears from the sound heard through their roofs. It is natural to suppose that many streams, finding no readier outlet, flow into subterranean cavities, are absorbed by the earth, or discharge themselves under ground into the sea. In this way may be explained the origin of those springs of fresh water that are to be seen spouting up even in the midst of the waves of the ocean. The waters thrown up by volcanoes, the sudden and terrible inundation of mines, the number of rivers which disappear, the mountains which are suddenly engulfed in the bosom of new lakes, — all these facts leave no doubt of the existence of extensive subterranean cavities containing large bodies of water. The digging of wells has supplied a fact still more interesting to physical geography. It appears that there are lakes, or rather sheets of water, which extend under ground to considerable distances. In digging wells near Aire, in the province of Artois, they always come to a clayey bed ; which being pierced, the water gushes forth in large bubbles, and forms permanent springs. In the country of Modeux, we find every where, at the depth of twenty yards, a bed of clay five feet thick ; which being pierced, the water spouts up with considerable force — indicating that it is connected with a reservoir which stands at a higher level. There is a district in the interior of Algiers, where the inhabitants, after digging to a depth of about 200 fathoms, invariably come to water, which flows up in such abundance that they call it the subterranean sea.

873. *Lakes which receive much water, but have no outlet, were long believed necessarily to communicate with the ocean by some subterraneous channel.* The great distance of some of them from the ocean seemed to stand in the way of such an explanation ; but doubts might still have remained, were it not for the discovery of the remarkable fact, that some of the principal lakes of this description have their surfaces far depressed below the level of the ocean. Thus the surface of the Caspian Sea, which is the largest known lake, and without an outlet, was found by Engelhardt and Parrot to be 334 feet beneath the level of the Black Sea. A similar depression has been ascertained of the level of the famous Dead Sea, in Judea, which is also a lake without an outlet. Its surface is below that of the Mediterranean in its neighbourhood, and consequently still farther below the higher level of the Red Sea. The true explanation as to the consumption of the waters of such lakes seems to be, that it is carried off by evaporation. The climates in which the two last-mentioned are situated accord well with this supposition. The level of these lakes, however, varies with the weather, and with the abundance or scarcity of the waters discharged into them by rivers at particular seasons of the year. The variation in the height of the Caspian Sea is from four to eight feet ; but the level, at a particular point of its shore, must be affected by the direction of the wind, and probably by a very trifling tide. When the banks of lakes are

very porous, they cannot fail, during very dry weather, to absorb a large portion of the water, and to throw it off by evaporation.

874. *The depth of great lakes has been seldom ascertained with much exactness.* The general depth of the Caspian Sea is from 60 to 70 fathoms; but this increases towards the south end to such a degree, that no bottom can be found with a line of 380 fathoms. In lakes, as in the ocean, the slope of the bank is continued downward for a considerable way below the water; that is, deep lakes are to be found in mountainous districts, and shallow marshy ones in flatter countries. The depth of Loch Ness, in the Highlands of Scotland, is in some places 130 fathoms, which is four times the mean depth of the German Sea; and its bottom is actually 30 fathoms below the deepest part of that sea, between the latitudes of Dover and Inverness.* The Lake of Geneva attains the still greater depth of 161 fathoms. Many other lakes are known to be exceedingly deep, without the amount being ascertained. Several have passed for ages as bottomless; but this opinion now obtains little credit. It is more probable, that most lakes are daily getting more shallow, from being filled up with mud or debris.

875. *The temperature of the surface of lakes depends on the climate and season;* but at the bottom of deep lakes it undergoes little or no change throughout the year, and approaches to that which corresponds to the maximum density of water, which different writers estimate variously, from 39° F. to 42·5°; but 40° is most commonly received. In Loch Catrine and Loch Lomond, the temperature, at all depths below 40 fathoms, is 41°; but the mean for the climate is 47°. The deep lakes of Thun and Zug, in Switzerland, had a temperature of 42° at the depth of 15 brasses. Thun was 41·5° at the depth of 105 brasses, while the surface was 60°; and Zug, 41° at 38 brasses, with surface 58°. The bottom of the Lake of Geneva has a temperature of 42°: that of the Lago Sabatino at Rome is 44·5°, at a depth of 80 fathoms. Tepid springs may, in some cases, keep up the temperature, when they occur at the bottom of lakes. From what we mentioned of the Caribbean Sea, it does not appear that the climate has much influence; and yet most powerful springs of fresh water are known to boil up in its shallower parts. Such springs probably approach to the mean temperature of the climate; or, perhaps, those who contend for an increase of heat with the depth of the solid strata would claim for them a higher temperature. Deep lakes almost never freeze, except in a very cold climate; because the whole body of water must cool below 40° before congelation could commence. Accordingly, neither Loch Ness nor its effluent river of the same name are ever frozen over.

876. *The qualities of the waters of lakes are various,* according to the nature of the substances with which they may be mixed or contaminated. The principal distinctions, in this respect, are *fresh, saline, and alkaline.* Lakes which receive much fresh water, and have a copious efflux, are almost always fresh; but those which lose much of their water by evaporation may be slightly saline, especially if the neighbouring soil abound in salt. When lakes have no outlet, they are invariably saline. To account for this, two reasons have been given, which are quite compatible with each other. The one is, that salt lakes having no outlet are concentrated portions of the waters of the deluge, retained by the hollows of the earth's surface; and that all other lakes were originally such, and saline; but those have had their salt washed out and carried to the ocean, which are traversed by rivers or other fresh water. The other opinion is, that the salt in lakes has come from springs, or been washed from the soil of the adjacent country by means of the rain and rivers: for such lakes are most abundant where the soil contains saline matter; and where lakes only lose water by evaporation, the vapour goes off fresh and leaves the salt behind. The Dead Sea is the saltiest of all known lakes, and appears to have been so for upwards of 4000 years; for in the book of Genesis it is called, by way of distinction, the "Salt Sea," even at a time when the adjacent plain was as noted for fertility as it is now for barrenness. The waters of this lake are in a state of saturation, containing about eight times as much salt as those of the ocean. The salt must be accumulating in beds at its bottom; for the river Jordan, which is brackish, necessarily carries in more. Masses of bitumen frequently float on the surface, and seem to rise from the bottom of the lake. The same thing occurs in other Asiatic lakes, some of which are impregnated with borax. In the island of Trinidad, there is a lake which produces an enormous quantity of bitumen fit for naval purposes.

877. *Some lakes are both saline and alkaline,* as is the case with a series of lakes in Lower Egypt. These are called the Natron Lakes, from their abounding in soda, which is there called *trona* and *natron*, the *nitre* of the Sacred Writings.

878. *Lakes appear to have been much more numerous at a former period than at present,* and to have occupied a large proportion of the surface of the land. Traces of their existence occur every where. Many of them have been filled up with debris, and become level plains traversed by a river; some have been drained by the gradual deepening of their outlets; or both causes have often operated together. Others have got vent through cracks caused by earthquakes, or by the subsiding of a part of the basin. The kingdom of Hungary is sup-

* Vide Stevenson, Wernerian Memoirs, and Edinburgh Phil. Journal.

posed to have been originally the basin of a lake; and some go so far as to allege the same of the Mediterranean Sea. Geological phenomena also show that new lakes arise, and old ones disappear, during those great risings and sinkings of the land which have taken place during former periods, and even now are not without example.

879. *There are several modes in which new lakes may be formed.* In hot tropical climates, many large lakes are formed during the rainy season, and entirely disappear on a change of weather; but such hardly deserve the name, being rather land-floods, though they would be permanent lakes in a colder country. We already mentioned the formation of a visible or open lake from the falling in of the roof of a subterranean one. When a mountain falls asunder, it often happens that it stops up a neighbouring river and valley, and forms a lake. But the water of a river obstructed in this manner will always overflow, and can scarcely fail to regain its former level, either by wearing away a cut for itself above, or by undermining the ruins beneath. Shallow marshy lakes are frequently formed by the surplus waters of rivers detained on flat ground by an accumulation of mud. Ice and snow sometimes accumulate in narrow passes between mountains, so as to obstruct and make the water stagnant, and form a temporary lake, increasing perhaps for years, till at length the pressure of the water is augmented to such a degree as to burst the icy barrier. The consequences are sometimes dreadful. So great a discharge of water and ice, precipitated from the mountains, tears up not only alluvial substances, but frequently portions of rocks, which are scattered over the plain below. Thus villages and fertile fields are almost instantly converted into deep hollows and heaps of rubbish. These cavities perhaps continue filled with water, forming small lakes.

880. *There are certain lakes which disappear and re-appear periodically,* without regard to the rainy season. Such are supposed to be filled and emptied in a manner similar to the cavities of intermitting springs, or to communicate with some subterranean lake which undergoes such periodical changes. That any lakes, remote from the sea, should communicate with it under ground, so as to rise and fall with the tide, is very improbable. In Portugal there is a small lake near Beja, which emits a loud noise on the approach of a storm. Other lakes appear agitated by the disengagement of gases. Near Boleslaw, in Bohemia, a lake of unfathomable depth sometimes emits blasts of wind which raise up pieces of ice. Some of the Scottish lakes, and the Wetter in Sweden, experience violent agitations even during serene weather. A coincidence of dates has given ground for believing that these agitations are connected with earthquakes in distant countries.

SECT. IV. *Rivers.*

881. *The origin and progress of rivers* has been compared by Pliny to the life of man. "Its beginnings are insignificant, and its infancy is frivolous; it plays among the flowers of a meadow, it waters a garden, or turns a little mill. Gathering strength, in its youth it becomes wild and impetuous. Impatient of the restraints which it still meets with in the hollows among the mountains, it is restless and fretful; quick in its turning, and unsteady in its course. Now it is a roaring cataract, tearing up and overturning whatever opposes its progress, and it shoots headlong down from a rock; then it becomes a sullen and gloomy pool, buried in the bottom of a glen. Recovering breath by repose, it again dashes along, till, tired of uproar and mischief, it quits all that it has swept along, and leaves the opening of the valley strewn with the rejected waste. Now quitting its retirement, it comes abroad into the world, journeying with more prudence and discretion, through cultivated fields, yielding to circumstances, and winding round what would trouble it to overwhelm or remove. It passes through the populous cities, and all the busy haunts of man, tendering its services on every side, and becomes the support and ornament of the country. Increased by numerous alliances, and advanced in its course, it becomes grave and stately in its motions, loves peace and quiet, and in majestic silence rolls on its mighty waters till it is laid to rest in the vast abyss." The sun and the host of heaven have, in all ages and nations, been objects of sincere worship. Next to them, the rivers seem to have attracted the grateful acknowledgments of the inhabitants of the neighbouring countries. They have every where been considered as a sort of tutelar deities, and each little district, every retired valley, had its river god, who was preferred to the others. The expostulation of Naaman the Syrian, who was offended with the prophet for enjoining him to wash in the river Jordan, was the natural effusion of this attachment. "What (said he), are not Abana and Pharpar, rivers of Damascus, more excellent than all the waters of Judea? Might I not wash in them and be clean? so he went away wroth." In those countries particularly where the labours of the husbandman and shepherd depended on what took place in a far distant country by the falling of periodical rains, or the melting of the collected snows, the Nile, the Ganges, the Indus, were the sensible agents of nature in procuring to the inhabitants of their fertile banks all their abundance, and they became objects of grateful adoration. Their sources were sought for even by conquering princes, and when found were worshipped with the most affectionate devotion. These rivers preserve to this day the fond adoration of the inhabitants of the countries through which they pass, and their waters are still held sacred.

882. *The term river* is applied to any large current of water which is not in the ocean or its branches, and which may discharge itself into the ocean, into lakes, marshes, or into other rivers; for the waters of some rivers never reach the ocean; as is the case with the Wolga, the Jordan, and others, which discharge themselves into salt lakes, having usually the name of *seas*. When the atmosphere supplies a country with more water than it has an opportunity of carrying off again by evaporation, the surplus either penetrates through the surface or collects into small streams, which, afterwards uniting and receiving the water of springs, gradually form larger and larger currents, which, if allowed to proceed increasing, at length become rivers. Some rivers proceed from lakes or marshes, but none come immediately from the sea. They invariably occupy the lowest parts of the districts from which their waters are derived, and these districts are called their *basins*. The basins are usually bounded by high lands, and sometimes by mountains. They form natural divisions in physical geography. Those of the Rhone, Garonne, Loire, Seine, and part of the basin of the Rhine, comprehend the greatest part of France. In some cases, the boundaries of basins are not well defined; as where the surface becomes flat or marshy. This is the case between the basins of the Amazons and Orinoco, which are connected by a natural and navigable communication. In Europe, the sources of the Dwina, of the Niemen, and of the Borysthenes, are nearly united in a marshy plain. It is evident that the deep ravines through which rivers flow could not in many instances be the work of the rivers themselves; because the margins of such ravines are often higher than other places of the district, through which the rivers ought to have flowed before such valleys were cut, as some fancy, out of solid rock. A more rational explanation is, that a crack or rent, — the effect of some earthquake or subsidence, — had taken place; and that the water, getting through such rent, had gradually widened it by the attrition of its sand and gravel: the still more corroding action of the weather would materially assist in widening the upper part of the ravine. Many rivers appear to have been at first a series of lakes and cataracts alternately, through which the water was conveyed from higher to lower ground. The bottoms of these lakes are gradually filled up with debris, the outlets are by degrees deepened, or the basins rent through as above described. The lakes at length become dry plains, traversed by the river; the cataracts, clefts or deep ravines: and the river acquires, upon the whole, a pretty uniform descent. There are traces of these changes every where: the parallel roads of Lochaber, as they are called, seem to be nothing else than the horizontal shelves with which lakes are usually surrounded. From these it appears that the valleys of Glen Gluoy, Glen Roy, and Glen Spean, have formerly been the basins of lakes, which are now cut through and emptied. Three distinct basins are observed in the course of the Rhine: first, that of the Lake of Constance; the second reaches from Basle to Bingen; and the third from this to the sea. They are separated from each other by rocky straits. In many cases, the subsidence of the water, at successive stages, can be traced from one level to another, by means of the different horizontal shelves still visible on the sides of the valleys. Sir Thomas Lauder remarked this, in the above named glens in the Highlands of Scotland. In the valley of the Rhine, Professor Playfair distinguished four or five such terraces, at the successive heights of twenty, thirty, or forty feet above one another. The same thing occurs on the banks in the great chain of North American lakes which are not yet empty.

883. *The larger rivers are, their fall or declivity is generally so much the smaller.* The reason of this is, that large rivers necessarily occupy the lowest parts of the country; and also, that there are no materials of which beds of rivers are ordinarily formed, that could have resisted the action of a great river, having a rapid fall, during the lapse of ages. In the last 200 leagues of the Amazons, the fall is only 10.5 feet; and in the 3000 miles above that, the mean fall is only five inches per mile. The Seine, between Valvins and Sevres, has a fall of about 9.5 inches per mile. The Loire, between Briare and Orleans, has only one foot on 13,596. Between the Himalaya chain and the sea, the Ganges has only four inches per mile. The entire fall of the Wolga is 957 French feet, or five inches per mile. Notwithstanding the rapidity of the Rhine, it has only a fall of four feet per mile between Schaffhausen and Strasburg; and of two feet between that and Schenckenschantz. Sometimes a river falling into another with great rapidity, and at an acute angle, will at the time of a flood force the latter to flow back for a short way. Such is sometimes the effect of the Arve on the Rhone, which is forced back into the Lake of Geneva.

884. *The bore* is a phenomenon which occurs on some great rivers, which enter the sea with considerable velocity, and experience a sudden check or obstruction from the flow of the tide: the consequence is, that an enormous wave, known by the term *bore*, and various other names, is generated and sent backward or up the river with great velocity, to the no small danger of the navigation. The principle on which this phenomenon depends is nearly allied to that of the hydraulic ram: at the spring tides, it appears of a correspondingly greater magnitude. In the Amazons, the height of this wave is estimated at 180 feet.

885. *Rivers are subject to inundation.* In the Sacred Writings, some allusions are made to the overflowings of the Nile; but those of the Jordan are distinctly mentioned, as covering all the banks during harvest, and expelling the lions which lurked in the thickets, so as to

drive them infuriated through the country. Modern travellers, however, assert that this river does not now overflow; and they allege as a reason, that its channel is become deep enough to hold the floods. It is as likely that the banks have been raised by the deposition of mud and the growth of vegetables: perhaps the fall of snow and rain upon Mount Lebanon, from which the floods came, is not so abundant since its forests of cedars were cut down; for some travellers are of opinion that this river must, from the accounts of the ancients, have been formerly of much greater magnitude, at all seasons of the year, than it now appears to be.

886. *The excessive rains* which fall in tropical regions, during a certain season of the year, occasion the inundation or overflowing of the rivers which originate in the torrid zone. The following is nearly the general rule for the rainy season; viz., that periodical rains every where prevail from the equator to the parallel of latitude over which the sun is vertical. Humboldt mentions as another pretty correct and still more general rule, applying likewise to the frigid zone, that the season of floods falls within four months of midsummer. The floods of rivers originating in high latitudes proceed principally from the melting of the ice and snow on the mountains, by means of the summer's heat. Such floods are violent, but of short duration, and occur in the four months preceding the summer solstice. Some of these rivers have two, or perhaps three, successive floods, corresponding to the seasons of thaw in the low ground, on the sides of mountains, and on their summits.

887. *The ancients* were quite aware that some rivers derived their floods from the sources we have just mentioned; but the overflowings of the Nile, in a country remote from both rain and snow, excited their surprise. The mystery was, however, dispelled, when once it was known that the Nile principally draws its waters from the tropical regions, where the excessive periodical rains cause other rivers to overflow. The Nile begins to swell in June, and continues to do so till the middle of August, when it has reached its maximum height of from 24 to 28 feet. With the exception of a few elevated spots, and some of the higher accumulations of alluvial matter, on the margin of the river, the whole of the Delta and the long valley of Egypt is then covered with water. The rising of the Ganges, which is partly owing to the melting of snow and partly to the rainy season, commences in April, and, like the Nile, attains its maximum of about 31 or 32 feet in the middle of August. Tropical rivers which move parallel to the equator spread their waters pretty uniformly over the low ground: such is the case with the Orinoco and the Senegal. In rivers which descend from great elevations, or move at right angles to the equator, the action of the tropical rains is extremely unequal; for the surplus water only overflows the low and flat districts. This is exactly what happens with the Nile: but it is sufficient here to mention the general principles; as the inundations of particular rivers will be described along with their respective countries.

888. *Waterfalls, or cascades and cataracts*, are often formed by rivers in descending from primitive mountains into secondary countries. Compact durable rocks are requisite for producing a permanent effect of this kind: such are the cataracts of the Nile, of the Ganges, and various other rivers. Some cataracts, like those of Zunguska, in Siberia, have gradually lost their elevation by the wearing away of the rocks, and have now only a rapid descent. According to Humboldt, the height of the great cataract of the Rio de Bogota, in South America, long estimated at 1500 feet, is about 800 feet; that of Staubbach is about 900 feet. The small river Ache, in Bavaria, which rises in the cavern of the glacier of Mount Tauren, runs through the valley of Achenthal, and, after reaching the Gulf of Tauren, throws itself over an elevation of 2000 feet. It has five great falls; the last of which forms a most magnificent arch of waters, which is resolved into spray before it reaches the ground. The noise of the waters is so terrible, that it is heard at the distance of more than a league; and the current of air produced by the descent of the water is so violent, that it drives back those who attempt to advance towards the gulf: it is necessary, therefore, to approach it by walking backwards. The fall of Garispa in India is 1000 feet. One of the most considerable known falls takes place on the river Niagara, which connects Lakes Erie and Ontario. The river here, just before the fall, is divided by Goat Island into two parts: the one, 600 feet broad, falls to the depth of 150 feet; while the other, 35 yards broad, falls 164 feet in perpendicular height. In Scotland the most considerable falls are those on the river Clyde, near Lanark, where the river is precipitated down three successive precipices of red sandstone. In the upper fall, that of *Bonniton*, the whole river throws itself over a precipice 30 feet high: lower down, at *Corra Linn*, it is precipitated from a height of 84 feet. The lowest fall, that of *Stonebyres*, consists of three stages, being broken by two projecting rocks; its fall is 80 feet. In the course of the river Foyers, on the side of Loch Ness, there are two falls; the upper fall is 40 feet high, the lower 90 feet. In the mineralogical report of Lapland, presented to the Swedish government, the discovery of a great waterfall in the river Lulea is particularly mentioned. It is said to be one eighth of a mile broad, and to fall 400 feet; if the mile be German, as is most likely (equal to four and a half English miles), the breadth exceeds half an English mile.

CHAP. III.

GEOGNOSE.

889. *This branch of natural history makes us acquainted with the structure, materials, relative position, and mode of formation, of the great mineral masses of which the crust of the earth is composed.*

890. *In conveying to our readers a short view of this important subject, we shall adopt the following arrangement:—*

- I. Describe the physiognomy of the earth's surface.
- II. Give an account of the action of water and air on that surface.
- III. Give an account of the action of volcanoes and earthquakes on the earth's surface.
- IV. Describe the different structures observable in the solid mass of the globe.
- V. Define and describe the different classes and species of rocks of which the crust of the earth is composed.

SECT. I. *Physiognomy of the Earth's Surface.*

891. *Dry land.* The dry land, or the land above the level of the sea, is arranged into masses of various magnitudes and forms. It is not equally distributed; for a much larger portion of it occurs to the north than to the south of the equator; and the difference in this respect is so great, that the southern half of the globe is principally water, while the northern is chiefly land. About the middle of the last century, it was asserted that a great continent must exist towards the south pole, in order to counterbalance the mass of land in the northern hemisphere; but by the voyages of Cook and Bellinghausen, and particularly the late enterprise of Weddel, it has been shown that in high southern latitudes, in place of a continent, there are but a few groups of islands. The absence of a continent near the south pole does not itself prove that there is less land there than in the north, since it is possible that the land in general may be only rather more depressed in the south, and consequently the ocean is spread more extensively over the surface of the earth in that quarter. The dry land is arranged into two grand divisions named *worlds*, viz. the *Old World* and the *New World*. The *Old World*, in the eastern hemisphere, extends from S.W. to N.E., and comprehends the three continents of Europe, Asia, and Africa. The *New World*, in the western hemisphere, extends from N. to S., and is composed of two continents, viz. North and South America.

892. *The general direction of the land in the two worlds is different.* In America, it is from N. to S.: in the *Old World*, it is S.W. to N.E.; and, if we omit Africa, it is almost parallel with the equator. The longest straight line that can be drawn on the *Old World* commences on the western coast of Africa, from about Cape Verd, and extends to Behring's Strait, on the north-east coast of Asia: it is about 11,000 miles in length. A similar line traced along the *New World* from the Strait of Terra del Fuego to the northern shore of North America measures nearly 9000 miles.

893. *The Old and New Worlds have the following features in common:* northern and southern halves, connecting isthmuses, a peninsula on the one side, and a group of islands on the other. This arrangement will appear evident from the following details.

894. *The old world may be considered as composed of two great halves:* the one, the western, includes Europe and Africa; the other, the eastern, Asia and New Holland. In the western half, the two continents, viz. Europe and Africa, are connected together by the isthmus of Suez, and have on the one hand the islands of the Mediterranean, and on the other the peninsula of Arabia. In the eastern half, the two continents of Asia and New Holland are, to a certain extent, connected together by the islands of Java, Sumatra, &c.; and in front of this *broken isthmus* is Papua and other islands, and on the other side the peninsula of India. The *New World* is composed of two halves, a northern and a southern: these are connected together by the isthmus of Darien; and on the front are situated the West India islands, and behind the peninsula of California.

895. *Another general feature in the general distribution of the dry land, is the tapering of all the great peninsulas to the south.* This, for example, is the case with the continent of Africa, with Arabia, India, South America, Scandinavia, Spain, Italy, Greece, Corea, Alashka, Kamschatka, California, Florida, and Greenland.

896. *Besides the Old and New Worlds, as above described, there occur, dispersed through the ocean, numerous smaller masses of land, forming islands of various magnitudes and forms.* Those islands situated near to the continents are considered as belonging to them. Thus the British isles belong to Europe, those of Japan to Asia, the West India islands to America, and Madagascar to Africa. But besides these there are other islands and groups of islands, situated at a distance from continents, and which cannot be referred to any of the preceding divisions, but to the oceans in which they occur; as, for example, the Sandwich Islands, in the North Pacific Ocean.

SUBJECT. 1. *Inequalities of the Surface of the Dry Land.*

897. *The surface of the land exhibits great variety in aspect, forming mountains, hills, valleys, and plains.* The most general of these features are what geographers term *high land* and *low land*. *High lands* are lofty, uneven, and widely extended masses of land: thus, the mountainous tract of country extending from the Naze of Norway to the North Cape is a high land. *Low lands* are widely extended low and flat countries: thus, the northern part of France, the Netherlands, Holland, part of Germany, and Silesia; Poland, and European Russia form what may be called the great European low land. We shall first explain the structure of high land, and next that of low land.

898. (1.) *Structure of high land.* In a high land, the central parts are generally the most rugged and lofty, while the exterior districts, those which border on the low land, are lower, and less rugged. The central part is named *alpine*, the lower and the exterior part *hilly*. The alpine part of a high land is composed of a central and lofty chain of mountains, named the *central*, or *high mountain chain*, towards which there tend a greater or lesser number of *lateral* or *principal*; and from these again *subordinate* chains. The high mountain chain forms the *water-shed* (*divortia aquarum*) of the district; and the hollows that traverse the upper part of this chain are named *passes* (*cols*). On passing from one side to another of the alpine land, we do not always travel through a pass or *col*, but sometimes across a comparatively flat tract, many leagues in extent; such are named *table lands*. In crossing from Norway to Sweden, we pass in some parts across a table land; also in travelling from Vera Cruz by Mexico to Acapulco. The inclined planes on which the lateral, or principal and subordinate, chains are distributed are named the *acclivities* of the high land. The hollows that separate these chains from each other are named *valleys*: those valleys bounded by principal chains are named *principal valleys*, and sometimes *transverse valleys*; while the valleys between subordinate chains are named *subordinate valleys*. The hilly or lower part of the high land is composed of comparatively low and less rugged chains, called *chains of hills*, which are irregularly grouped, being entirely without a central or high mountain chain. The valleys in this hilly land are shorter, less steep, and not so rugged as in the more central or alpine part of the high land.

899. (2.) *Structure of low land.* Low land is formed principally of extensive plains, little elevated above the level of the sea, in which we occasionally observe gentle risings and undulations of the surface, that often extend to a considerable distance, and sometimes form the limits between neighbouring rivers. Now and then conical and table-shaped hills rise up singly and suddenly in low country, as is the case with volcanic and igneous hills. The plains of the low land are characterised by the presence of particular hollows or concavities, which are named *river-courses* or *river-valleys*; because in these rivers flow. In such hollows we distinguish the *bed* of the river, and the *holm* or *haugh land*; further we observe the *high* and *low* banks of the river, and the *ravines* or small valleys, that traverse the high bank and terminate in the low bank. There is still another kind of hollow met with in the low land; it is that in which lakes, generally shallow, are contained.

900. *Coasts.* The margin of the dry land, where it meets the waters of the ocean, has received the general name of *coast*. It varies in its aspect. Sometimes it is low and shelving, and then the neighbouring sea is shallow to a considerable distance; at other times it is steep, lofty, and rugged, and then the sea is deep. In many parts of this country, and on the continent, as in Holland, the coast is low and sandy, and the sand is occasionally blown into hills.

901. *Caves.* These are cavities of greater or less extent, which are either *open* to day, as in the case of the magnificent caves in the Isle of Isla, those in Arran, those near Wemyss on the coast of Fifeshire, &c., when they are named *external* or *open caves*; or they are more or less concealed in the interior of the rocks in which they are contained, as Maclean's Cave in the Isle of Egg, and many caves in the limestone of Derbyshire: such are named *internal caves*.

SUBJECT. 2. *Inequalities of the Surface of the Submarine Land.*

902. *The bottom of the sea, like the surface of the dry land, varies in form.* In some seas there occur flats and plains ranging to a considerable extent, and near to the surface of the water, forming what are called *shoals*; in other cases, plains, of great extent, occur deeply seated, or much below the surface of the sea, which are denominated *deep submarine plains*. These submarine plains, like the plains on the dry land, sometimes contain hollows of considerable extent, and of great depth; the deep hollows under the sea off the east coast of Scotland, known under the name of *Montrose pits*, are of this description. The sea bottom is sometimes *hilly*; these hills vary in form and magnitude, and are either deeply seated, or rise above the surface of the water, forming rocks or islands. In tropical seas, the bottom, when not very deep, becomes encrusted with coral; which coral sometimes rises to the surface, and then forms *coral shoals*, *coral reefs*, or *coral isles*. If the bottom is very deep, but sends up from below hills whose summits are not far below the level of the ocean, these in tropical seas also become covered with coral.

SECT. II. *Effects of Water and the Atmosphere on the Surface of the Land.*

903. *Water* is a very active agent in altering and variously modifying the surface of the earth, and its energy is increased when it carries along with it mechanical matter, as sand, gravel, &c., and particularly when aided by the gnawing influence of the atmosphere. Through these agents the whole surface of the dry land is kept more or less in a state of motion, by their breaking up the strata, and removing with greater or less rapidity, the broken rocky matters from point to point, and often into lakes and the sea.

904. *Water acts mechanically and chemically*: it acts *mechanically* when it removes part of the soil or broken rocky matter over which it passes, or corrodes the channel in which it flows, or the reservoirs in which it is contained; it also acts mechanically, when, on being imbibed by rocks, it increases their weight, and thus favours their rending, slipping, and overturning; and, lastly, it acts mechanically, when, by its freezing in fissures, it breaks up mountain masses and rocks. It acts *chemically*, when it dissolves particular mineral substances, as rock-salt, out of the rocks through which it percolates.

SUBJECT. 1. *Mechanical destroying Effects of Water.*

905. (1.) *Rivulets and rivers.* Running waters, in their course from the higher to the lower parts of a country, carry along with them the debris already prepared by the action of the weather on exposed rocks, and also more or less considerable portions of the strata of the basin in which they flow. The quantity of abraded matter depends in a great degree on the quantity of sand or gravel the river carries along with it; it being a fact, that running water, when pure, acts but feebly on compact strata, and displays its scooping or excavating power only when carrying along with it sand, gravel, and such other matters, which communicate to it a mechanical destroying action. As the velocity of the river diminishes its carrying power diminishes; and frequently, long before it has reached the marsh, lake, or the sea into which it disembogues itself, it carries only slime and sleet, leaving the gravels and larger solid masses in higher parts of its course. The transporting power of water is much greater than many are aware of: it is strikingly shown by the enormous quantities of rubbish, and great blocks of stone, which are swept along by rivulets when in the state of flood or swollen. This transporting power is materially assisted by the diminished specific gravity of the rocks when immersed in the water, by which their weight is often diminished one third, and even one half. The transporting of heavy stones by water in situations where ice occurs is assisted by the ice which adheres to them, and which diminishes the specific gravity of the mass. Some curious details in regard to this subject are given in one of the volumes of the *Memoirs of the Wernerian Natural History Society*. The late Professor Robison, the most profound and learned teacher of natural philosophy Scotland ever produced, in his admirable article on Rivers, in the *Encyclopædia Britannica*, has discussed with great ability many circumstances connected with the progress of rivers, but which our limited space prevents us from noticing.

906. (2.) *Lakes.* Around the margins of many lakes we observe a beach, formed of the fragments of the neighbouring strata, broken off in part by the waters of the lake. The bursting of lakes also occasions great changes in the neighbouring country, which changes are of a mechanical destroying nature.

907. (3.) *Ocean.* The waters of the ocean exercise a powerful destroying effect on coasts. If the coasts are bold and rugged, they are violently assaulted by the waves of the ocean; the crags and cliffs split and tumble down, in frightful and irregular succession. The perforated rock, the Doreholm, on the west coast of Shetland; the perforated rocks described by Captain Cook near New Zealand; the stalks, holms, and skerries on the coasts of Shetland, Scotland, and Norway, are effects of the destroying power of the waves of the ocean, conjoined with the gnawing action of the weather. The various inroads of the sea on the east and west coasts of Scotland are well detailed in Mr. Stevenson's memoir, read before the Wernerian Society; those on the east and west coasts of England are also considered by Stevenson, and by Young and Phillips, in their *Geologies of Yorkshire*; by Taylor, in his *Geology of East Norfolk*. On those rocky coasts where the strata are of unequal hardness, the softer portions, and also part of the surrounding harder mass, are removed by the action of the waves; and thus *sea-caves* are formed.

908. *The waters of the ocean often also cause dreadful ravages in low countries exposed to their fury.* Holland furnishes many striking examples of its devastating power. In the year 1225 the waters of the ocean, agitated by a violent tempest, inundated the country; the Rhine, swollen at the time by extraordinary floods, and retained at a great height, partly by the waters of the ocean, and partly by the wind blowing in a contrary direction to its course, spread over the neighbouring country: but, the tempest having suddenly subsided, the highly elevated waters retired, with such velocity and force as to carry with them a considerable portion of the soil, and left in its place the sea now named the *Zuyder Sea*. In

the year 1421, a great inundation submerged the southern part of the province of Holland, drowned 60,000 persons, and on retiring formed the *Bies-Boos*.

909. *The action of the sea on the submarine land* is also worthy of notice. Stevenson speaks of agitations of the sea reaching to a depth of upwards of 200 ft; stating that, at a considerable depth the power of the ocean is so considerable as to break rocks in pieces, and throw them upon the coasts in masses, of various sizes and forms. Thus he says, "numerous proofs of the sea being disturbed to a considerable depth have also occurred since the erection of the Bell Rock Light-house, situated upon a sunken rock in the sea, twelve miles off Arbroath, in Forfarshire. Some *drift-stones* of large dimensions, measuring upwards of thirty cubic feet, or more than two tons weight, have, during storms, been often thrown upon the rock from the deep water. These large boulder-stones are so familiar to the light-house keepers at this station, as to be by them termed travellers.* On the coast of the *main land* of Shetland, particularly on the west coast, we have observed many striking displays of the power of the waves in moving enormous masses of rocks.

910. *The currents* that traverse the ocean, like rivers on the dry land, probably scoop out beds for themselves, and carry away, and often to distant places, great quantities of abraded matter. The gulf stream, and other branches of the great equinoctial current, may act powerfully in this way; and the same may be the case with the currents in our own seas, and those that enter mediterranean seas and wind round them, as the Baltic and Mediterranean.

911. (4.) *Action of water by its own weight.* Water by its own weight contributes very much to the degradation of the surface of the globe. Sometimes great masses of rock, particularly those of a soft and porous nature, imbibe much water, by which their weight is increased, and thus occasions breaking and rending, and slipping of masses often of enormous magnitude. Clay beds sometimes become soft from the percolation of rain or snow water from the superincumbent strata. When this takes place the superincumbent beds lose their support, and if the clay and superimposed rocks are inclined at a considerable angle, the rocks in vast masses separate, and slide down into the lower part of the country. The fall of the Rossberg, in Switzerland, in September 1802, may be mentioned as an example of this phenomenon. This mountain (Rossberg) is 5193 feet high, and lies opposite to the Rigiberg, which rises 6182 feet above the level of the sea. The Rossberg is composed of molasse, with beds of clay, and all inclined at an angle of 45° to 50° . It is said that the clay in some of the beds was much softened by the percolating water, and the thick superincumbent beds of molasse, in this way losing their support, were separated from the inclined and soft surface underneath, and slid into the valley below. This avalanche of debris and mud overwhelmed several villages, and destroyed from 800 to 900 persons. In the year 1714, the west side of the Diablerets, in the Vallais, separated, and in its course downwards covered the neighbouring country with its ruins for two miles in length and breadth; the immense blocks of stones and heaps of rubbish interrupted the course of the rivers, and lakes were thus formed. In the year 1618, the once considerable town of Pleurs, in the Grisons, with the neighbouring village of Schelano, were overwhelmed by a vast mass of rock, which had imbibed much water, and separated from the south side of the mountain of Corto.

912. (5.) *Effects of the freezing of water.* In those regions of the earth where the freezing and thawing of water takes place, the expansive and destroying action of ice is often displayed on a grand scale. In the history of northern countries we meet with many accounts of the noises and rendings of rocks, occasioned by the expansion of water during its freezing in the fissures of rocks. Terrible disasters take place in alpine countries by the bursting and fall of great masses of rock, split by the freezing of the water in rents.

913. (6.) *Destroying effects of ice and snow.* Water in the form of ice causes considerable changes on the surface of the earth. Thus, when floated along in great masses by rivers, it breaks up their banks, and thus affords them an opportunity of devastating the lower country; and the masses are often so great, that enormous heaps of the strata are thereby torn off and carried to a distance. When sea ice is drifted against the cliffs and precipices on the coast, the breaking and destruction it occasions sometimes almost pass belief. For the breaking up and moving of large masses of rock, one of the most powerful engines employed by nature are the glaciers. These masses of congealed water and snow, in their course downward, push before them enormous quantities of broken rocky matter, which form great mounds, named, as formerly mentioned, moraine.

SUBJECT. 2. *Chemical destroying Effects of Water.*

914. *Atmospheric water* enters into the fissures of rocks in a pure state, but issues forth again more or less impregnated with mineral matters of various kinds abraded from the strata through which they pass. The most abundant substance brought out in this way from the interior of the crust of the earth is lime, which is deposited from these calcareous waters in the form of tuffa. Many of the excavations in limestone are partly owing

* Vide Wernerian Soc. Memoirs, vol. iii.

to this destroying effect of water. Spring waters, in passing through beds of gypsum and rock salt, dissolve a portion of them, and in this way sometimes occasion considerable changes in the interior and even the surface of the earth, by the superincumbent strata yielding over the hollows formed by the removal of the salt and gypsum.

SUBJECT. 3. *Mechanical forming Effects of Water.*

915. (1.) *Forming effects of springs.* Springs bring from the interior of the earth muddy matter of various descriptions; and in the course of time, if the springs are spouting-springs, hillocks and hills of considerable magnitude are thus formed.

916. (2.) *Lakes.* When lakes are filled up, or are emptied, we find the space formerly occupied by them covered, to a greater or less depth, with the alluvial matter brought into them by the rivers that flow into them. When lakes burst their barriers, at different times, they leave on their sides a series of natural terraces or platforms, of which we have a splendid example in Glen Roy. In Glen Roy these terraces are known under the name *Parallel Roads of Glen Roy*; because some have fancied they were not natural arrangements, but works of art, — roads formed by the ancient inhabitants.

917. (3.) *Rivers.* When rivers are in a state of flood they often overflow their banks, and cover the neighbouring country with their waters. Thus the Ganges, near its mouth, in the rainy season overflows the country to the breadth of one hundred miles, and to a depth of nearly twelve feet; and the Indus, during its period of inundation, extends thirty or forty miles from its banks. This flood water carries with it muddy and other matters, and deposits them upon the land. Gerard says that the annual floods of the Nile had raised the surface of Upper Egypt about six feet four inches, English measure, since the commencement of the Christian era, or four inches in a century. In other countries extensive deposits, extending along the sides of rivers, are formed by the overflowing of their waters. Where rivers enter lakes and the sea, they form triangular pieces of land named *deltas*, from their resemblance in form to the triangular-shaped Greek letter Δ . These deltas are more strongly marked in lakes than in nearly enclosed seas, as the Mediterranean; and in these seas than in the ocean, where the depositions are much interrupted by currents. The most famous in history of these deltas is that of the Nile. This delta has been considerably enlarged since the time of Herodotus, but not to the extent stated by many writers. At no great distance from the shore of the delta the depth of the Mediterranean is about seventy-two feet, and further out the sea suddenly deepens to 2000 feet, — a depth very probably beyond reach of the delta, and which may be conjectured to be the original depth of this part of the Mediterranean sea. The deltas of the other rivers that flow into the Mediterranean, as the Rhone and the Po, exhibit phenomena similar to those observed in the delta of Egypt; and by their considerable extent, and annual growth, furnish ample proofs of the forming power of rivers, and of the resemblance of alluvial matters to strata of an older date. The great sea-deltas, or those formed where rivers flow into the ocean, are sometimes on a great scale, as is the case with the Ganges, of which a most interesting account has been given by Rennel and some other writers. A full description of this magnificent delta, as also of the vast deposits at the mouths of the Mississippi, Orinoco, and other great rivers, will be given in the body of this work. At present, however, we may remark, that the quantity of matter carried into the sea by all the rivers of the globe is very great, and fully as considerable as that stated by some authors, who have been held as exaggerating the amount of this earthy matter carried from the dry land to the shores of the ocean. The alluvial matter brought down by rivers not only forms great tracts of land at their mouths, but also, through the agency of currents, assisted by the waves of the ocean, gives rise to extensive tracts of low and flat land, which extend along the coasts.

918. *Downs.* When the sea-coast is low, and the bottom consists of sand, the waves push this sand towards the shore, where, at every reflux of the tide, it becomes partially dried, and the winds, which often blow from the sea, drift up some portions of it upon the beach. By this forming action of the ocean, sandy flats and *downs*, or ranges of sand-hills, are formed along the coast. When this sand is moved about by the wind, it forms what is called the *sand-flood*. Westward from the mouth of the river Findhorn, in Morayshire, a district consisting of upwards of ten square miles of land, which, owing to its fertility, was once named the Granary of Moray, has been depopulated, and rendered utterly unproductive by the sand-flood. This barren waste may be characterised as hilly; the accumulations of sand composing these hills frequently varying in their height, and likewise in their situations. The sand hills of Barry, at the mouth of the Tay, composed of blown sand, are from 200 to 300 feet high. Belhelvie links, in Aberdeenshire, and the extensive sandy tracts in the Shetland and Western Islands, are of the same description. These blowing sands sometimes block up the mouths of rivers and rivulets: thus, many years ago, the mouth of the river Findhorn in Moray having become blocked up with blowing sand, it cut out for itself its present channel, which conducts it by a more direct course to the sea. In consequence of this the old town of Findhorn had changed its situation, from the east to the west side of the river, and its site has since been covered by the sea. The lake at Strathbeg, which covers

a square mile of country, on the coast of Aberdeenshire, about ten miles north from Peterhead, was formed about 170 years ago, by the choking up by blowing sand of a small stream that fell into the sea. These barriers sometimes give way, when the tract is again, for a time, covered by the sea; a new barrier again rises, and the sea is excluded a second time. These operations, on a great scale, would afford alternation of productions of the land and of the sea. The sands of the African deserts may be sea sands, or land sands, or both together. Dr. Oudney, Major Denham, and Captain Clapperton have added to our knowledge of the blowing sands of the African deserts. The coloured engraving of the sand-hills of the African desert in Denham, Oudney, and Clapperton's Narrative, is a striking and interesting representation of the form of the moving sand-hills of Africa.

919. *Sand banks.* The bed of the German Ocean supports many accumulations of sand, called sand-banks. One of these extends from the Firth of Forth, in a north-easterly direction, to a distance of 110 miles, while another, the Dogger Bank, extends, north and south, for upwards of 350 miles. The average height of these submarine sand-banks is estimated at about seventy-eight feet: the whole surface of the various shoals in this sea laid down in charts, according to Stevenson, is equal to about one fifth of the whole area of the German Ocean, or about one third of the whole extent of England and Scotland. These banks are composed of quartz sand, varying in the size of the grain, from coarse to fine, which is abundantly mixed with broken shells and fragments of corals. These banks are conjectured to owe their origin to the action of currents and the tides.

SUBSECT. 4. *Chemical forming Effects of Water.*

920. (1.) *Springs.* Many spring waters, after dissolving, by means of the superabundant carbonic acid with which they are impregnated, calcareous matter abraded from limestone rocks, or rocks containing lime, allow the carbonate of lime to crystallise, in consequence of the escape of the acid, and in this way form depositions of calc-sinter, or calcareous alabaster, on the roofs, sides, and floors of caves; or fill up fissures in rocks, and form veins; or when flowing over the surface of rocks, form, if the surface is horizontal, horizontal beds — if inclined, inclined beds — of calcareous sinter and calcareous tuffa. These beds sometimes extend very far, and with a thickness of 200 or 300 feet. The water of such springs, when collected into hollows so as to form lakes, often deposits vast quantities of calcareous sinters and tuffas; and hence such lakes, when emptied, present extensive calcareous deposits. The travertine employed at Rome for building is a lake or spring calcareous deposit of sinter and tuffa; and the town of Guancavelica in South America is built of a compact calcareous tuffa from the calcareous springs in the neighbourhood. In the mountain limestone districts in England, also in the lias districts both in England and Scotland, the roofs, walls, and floors of caves are often elegantly ornamented by numerous varieties of calcareous sinter. In Persia, as mentioned by Sir John Malcolm, there are great deposits of a very fine calc sinter, which is extensively employed for ornamental purposes; and in the marshes of the great plain of the vast circular valley of Hungary, according to Bendant, there is a constant deposition of horizontal strata of calcareous tuffa and sinter, which are so hard as to be used for building, all the houses of Czelea being constructed of these minerals. The pea-stone, a beautiful calcareous carbonate, is formed in very considerable abundance from the waters of calcareous hot springs, as those at Carlsbad in Bohemia. As these calcareous springs often flow into rivers, and these rivers terminate in the sea, it is evident that in this way a vast quantity of carbonate of lime must reach the ocean, where it will be deposited in the various forms of sinter, tuffa, and limestone. The Geysers, or hot springs of Iceland, and those of St. Michael's in the Azores, deposit on the dry land vast quantities of siliceous sinter. This siliceous mineral, which is sometimes like opal, although generally pure, is not always so, being occasionally intermixed with other earths, and thus giving rise to particular mineral substances. Such springs also pour their waters into the ocean, and even rise from the bottom of the sea sometimes a considerable way upwards, or even jet above the surface level of the sea, all the time throwing out much water impregnated with silica, which is deposited on the submarine land in various forms and states, depending on a variety of circumstances which our limits prevent our noticing.

921. (2.) *Lakes.* Having already noticed the calcareous depositions from the waters of some lakes, we may now mention some other deposits that appear to owe their origin to lakes. The bog iron-ore, or hydro-phosphate of iron, is often found in such situations as to show that it has been deposited from the waters of lakes; and in some countries it is collected from the sides and bottoms of lakes once in a certain number of years; thus showing that it is still forming in such situations. In salt lakes considerable depositions of salt take place; and when such collections of water dry up, or are drained off, the sides and bottoms of the hollows are found incrustated with salt, which is sometimes disposed in beds alternately with beds of clay.

922. (3.) *Marine incrustations.* Collections of perfect and broken sea-shells and of corals are sometimes found agglutinated by calcareous, clayey, or ferruginous matters, forming banks or beds of considerable extent. Beds of this kind, particularly those formed of shells, are

met with in many parts of the coasts of this island. In other countries, as in the West Indies, a solid conglomerate of shells and corals lines a considerable extent of coast on several of the islands. The human skeleton from the island of Guadaloupe, in the British Museum, is imbedded in a rock of this description.

SUBJECT. 5. *Effects of the Atmosphere, &c.*

923. *Effects of the atmosphere.* The air and moisture of the atmosphere effect great changes on the rocks at the surface of the earth. They either simply disintegrate the rock, or not only break it down, but also occasion a change in its chemical constitution. Sandstone, and other rocks of the same general description, often yield very readily to the weather; their basis or ground is washed away, and the quartz, mica, and other particles remain in the form of sand and gravel. When trap veins intersect strata, it frequently happens that the softer parts of the rock are destroyed, while the harder trap appears rising several feet or yards above the neighbouring surface, and crossing the country like walls; hence, in Scotland, they are named *dykes*. The variously shaped *summits* of mountains and hills owe much of their form to the destroying influence of the weather. Some caves, as certain open caves in sandstones and limestones, are also formed by the destroying powers of the atmosphere. The various changes in the form of rocks, by which they assume columnar, globular, tabular, and indeterminate angular forms, and fall into *scales, crusts, layers, gravels, and sands*, are, to a certain extent, effects of the destroying powers of the atmosphere. Valleys owe much of their form and extent to the destroying influence of the atmosphere. Their sides and summits, every where exposed to its action, become covered with debris; and in this way valleys experience greater changes than are produced on their bottom by the passage of the river, and on its sides by the rushing of the torrent. The chemical destroying effects are to be traced to the carbonic acid of the atmosphere, and to the vast quantities of the same matter which rise from the interior of the earth: this acid dissolves lime, abstracts alkaline matters from granite and other similar rocks, and by combining with iron, converts that universally distributed substance into a soluble carbonate. The oxygen of the atmosphere also, by its action on the iron and other constituents of rocks, assists in breaking them down.

924. *Effects of electricity on rocks.* Electricity, as a chemical agent, may be considered not only as directly producing an infinity of changes, but also as influencing almost all that take place. There are not two substances on the surface of the globe that are not in different electrical relations to each other; and chemical attraction itself seems to be a peculiar form of the exhibition of electric attraction: and whenever the atmosphere, or water, or any part of the surface of the earth, gains accumulated electricity of a different kind from the contiguous surfaces, the tendency of this electricity is to produce new arrangements of the parts of those surfaces. Thus, a positively electrified cloud, acting even at a great distance on a moistened stone, tends to attract its oxygenous, or acidiform, or acid ingredients; and a negatively electrified cloud has the same effect upon its earthy, alkaline, or metallic matter; and the silent and slow operation of electricity is much more important in the economy of nature than its grand and impressive operation in lightning and thunder.

SECT. III. *On Volcanoes, and the Changes they produce on the Land and the Bottom of the Sea.*

925. *The agents which the globe conceals in its interior, and whose existence is manifested at its surface, are made known to us by the phenomena of volcanoes and earthquakes.* We shall first describe these phenomena, and afterwards add some observations on their causes.

SUBJECT. 1. *Distribution of Volcanoes.*

926. *Volcanoes, as is well known, are openings in the crust of the earth, whence there issue from time to time jets of burning substances and currents of melted matters which bear the name of lavas.* These openings are generally on the summit of isolated mountains; they have the form of a funnel, and take the name of *craters*.

927. *Position of volcanoes.* Volcanoes occur in all quarters of the globe, and are often distributed in a linear direction.

928. *Distribution.*—Europe contains but few burning volcanoes. On the coast of Sicily, we see *Ætna* rising like a colossus to a height of 10,870 English feet. On the opposite coast of Italy we have *Vesuvius*, which does not attain more than the third of this elevation, viz. 3932 feet. Between them, in the Lipari islands, we find the small volcano of *Stromboli*, and the volcanoes of *Vulcano* and *Vulcanello*, which still smoke. The islands of the Archipelago, at *Milo* and *Santorino*, contain mountains which, during an early historic period, produced terrible igneous phenomena. Iceland in the north, in the midst of snow and ice, presents to our view many volcanoes, of which the most prominent, *Hecla*, rises to a height of 5000 feet. Farther to the north, in the desolate and dreary

Jan Mayen's Island, extending between north latitude $70^{\circ} 49'$ and $71^{\circ} 8'$, is the volcano of Esk Mount, which rises to a height of 1500 feet above the sea-beach in Jameson's Bay. The continent of *Asia*, as far as is known at present, exhibits but few volcanoes. We can scarcely reckon three or four on its eastern shores, or on the edges of the Caspian: there are none in its northern part: some but vaguely known exist in Central Asia: in the east, the peninsula of Kamtschatka contains five or six; but in the islands which surround this continent their number is great. The islands on the coast of *Africa*, such as Bourbon, Madagascar, the Cape de Verd Islands, the Canaries, and the Azores, also contain several volcanoes. In *America*, if we except those of the West India islands, we observe the greater part of them on the ridge of that great Cordillera, which, like an immense wall or lofty terrace, borders the western part of that continent. They are remarkable not only on account of their position, but also for their colossal form, the nature of the masses of which they are composed, and the materials they throw out. Torrents of fire rarely issue from them, but streams of water and mud are of frequent occurrence: the total number of American volcanoes is about eighty-six; they are placed as it were in groups. The kingdom of Guatemala presents about twenty; in Mexico there are six, in the number of which is the Jorullo, so well known from the account of Humboldt. But it is in Peru that the greatest occur: there are seven in that country, of which we shall mention Pichincha, nearly 15,931 feet high; Cotopaxi, which rises to the height of 18,867 feet; and Antisana, which attains a height of 19,136 feet. On a rough estimate, we state the number of burning volcanoes including solfataras at 303; of these 194 are in islands, and the other 109 are on the continents: the most distant from the sea are those of America and Asia; in Peru there are volcanoes thirty leagues from the sea; and that of Popocatepec near Mexico, which, however, is now only a smoking volcano, is fifty-six leagues; and they occur in the very centre of Asia. The circumstance of the most active volcanoes being situated in the vicinity of the sea, is a fact worthy of being recollected; it becomes still more so when we observe, that there are submarine volcanoes burning in the midst of the waters. The islands, and the phenomena which they have been observed to produce, at Santorino, on the coast of Iceland, in the Azores, &c., leave no doubt respecting their existence.

929. *Independently of volcanoes in a state of activity*, the interior of our continents contains a great number of *extinct volcanoes*, but which still present their original form, or incontestable remains of that form: perhaps no country contains more numerous and splendid displays of them than France; there are more than a hundred in Auvergne, Vivarais, and Cevennes. They are conical mountains, composed of lavas, scoriæ, and volcanic ashes heaped upon each other; many of them present a crater, which has retained its form in a greater or less degree; and sometimes there are seen as it were issuing from their bases lavas which extend to a distance of several thousand yards, and which have perfectly preserved the form of *currents*: the matter of which they are composed resembles that of lava trap. We may further remark, that volcanoes are never or scarcely ever isolated; they are collected into groups. This is the case with the American volcanoes; those of Asia, and the different Archipelagoes are similarly situated: in Europe, the Greek islands and southern Italy present distinct groups. Sometimes volcanoes are arranged one after the other in the same line, as is the case in South America, and in the extinct volcanoes in the neighbourhood of the Puy de Dôme.

SUBJECT. 2. *Phenomena and Theory of Volcanoes.*

930. *Volcanoes do not incessantly emit flames*, nor do lavas constantly flow from them; they remain for ages in a state of inactivity. Vesuvius was extinct from time immemorial, when, awakening from its slumber, it suddenly re-kindled, in the reign of Titus, and buried the cities of Pompeii, Herculaneum, and Stabiae under its ashes. It became quiet again at the end of the fifteenth century; and in 1630, when it resumed its action, its summit was inhabited, and covered with wood. The inhabitants of Catania regarded as fables the accounts of history respecting eruptions of *Ætna*, till the period when their city was ravaged, and in part destroyed, by the fires of that volcano.

931. *Subterranean noises*, and the appearance or increase of smoke, which issues from the crater, are generally the first symptoms of volcanic action. Presently the noise becomes louder, the earth trembles, it experiences shocks, and every thing proclaims that it is in labour. The smoke increases, thickens, and becomes charged with ashes. When the air is tranquil, the smoke is seen rising, under the form of an immense column, to a very great height. There, finding itself in a rarer atmosphere, it ceases to rise; its upper part dilating, forms as it were an expanded summit, placed upon a lengthened shaft. The cloud, with the supporting column, in favourable circumstances, has the figure of an immense umbrella, or of the Italian pine, to which Pliny the Elder compared that of the eruption of Vesuvius in A.D. 79, and which was accurately represented in October, 1822. At other times the smoke disperses in the air: it there forms thick and vast clouds which obscure the day, and cover the surrounding country with darkness. These columns and clouds are often traversed by

enormous jets of red-hot sand, resembling flames, and rising to extraordinary heights. Sometimes they are traversed by flashes of lightning, and on all sides loud explosions are heard. Then there are projected red-hot stones and masses in fusion. They issue from the volcano with a noise which is frequently very loud. They rise into the air, spreading out in their progress, and fall around the mouth of the volcano under the form of showers of ashes, scoriæ, or stones. The shocks and quakings of the ground continue and increase in violence. In the midst of these convulsions, and on these accessions, the melted matter which filled the subterranean furnaces, already carried into the mountain, is raised up by elastic fluids; it ascends to the crater, fills it up, and passing over the least elevated part of this enormous cavity, spreads out upon the flanks of the volcano. It then descends, sometimes very quickly; sometimes, and more frequently, as a majestic river, quietly rolling along its peaceful waters. Very frequently, when the lava rises, the walls which contain it being unable to resist its immense pressure or its heat, give way and burst asunder. It rushes forth like an impetuous torrent through this new aperture: rivers and torrents of fire make their way to the foot of the mountain; they spread out upon the neighbouring ground, carrying along or burning all that they find in their way, breaking down or overthrowing every obstacle that opposes their passage. In the midst of torrents of fire, enormous currents of water and mud sometimes issue from volcanoes, and deluges falling from the atmosphere increase the ravages, lay waste fields which lavas had spared, and carry desolation into places which had already thought themselves happy in having escaped the scourges of the eruption. Mephitic gases and noxious exhalations sometimes arise, particularly in low situations; they destroy animals and blast vegetation, and thus complete the scene of misery and desolation.

932. *After the emission of the lavas the earth seems freed of the evil which agitated it, the earthquakes cease, the explosions and ejections diminish for some time, and the volcano enjoys a moment of rest: but presently a new accession takes place, reproducing in a still more terrible manner the same phenomena; and this state of things continues during a variable period of time. At length the crisis ceases, and the volcano finally resumes its original tranquillity.*

933. *Having premised this general account of volcanic action, we shall next treat of the substances ejected or projected into the atmosphere by volcanoes, and of the lavas which they pour out.*

a. *Ejected Matters.*

934. These are, 1. Smoke. 2. Ashes. 3. Sands. 4. Scoriæ. 5. Volcanic bombs. 6. *Unaltered Masses?*

(1.) *Smoke.* The enormous columns of smoke which are seen issuing from the crater, sometimes with extraordinary rapidity, are chiefly composed of aqueous vapour. This vapour is generally charged with gaseous substances, and particularly with hydrogen gas, sometimes also with carbonic acid. Sulphurous acid and muriatic acid are also given out. The smoke is grey or white; sometimes also brownish black, or fuliginous, and then the smell is not unlike that of asphaltum, or mineral pitch. It often contains a great quantity of volcanic ashes.

(2.) *Ashes.* These ashes, which appear to be nothing else than the substance of the lava reduced to a state of minute mechanical division, are formed of flocculent and extremely minute particles of a grey colour, and forming a paste with water. They are always mixed with a greater or less quantity of sand, which gives them the blackish colour which they sometimes exhibit. The torrents of gas and vapour which issue from the craters carry these ashes along with them, bearing them into the atmosphere, where they form vast clouds, sometimes so dense as to cover the surrounding country with darkness. During the eruption of Hecla in 1766, clouds of this kind produced such a degree of darkness that at Glaumba, which is more than fifty leagues distant from the mountain, people could only find their way by groping. During the eruption of Vesuvius in 1794, at Caserta, four leagues distant, people could only walk by the light of torches. On the 1st of May, 1812, a cloud of volcanic ashes and sand, coming from a volcano in the island of St. Vincent, covered the whole of Barbadoes, spreading over it so intense a darkness, that at mid-day, in the open air, one could not perceive the trees or other objects near him, nor even a white handkerchief placed at the distance of six inches from the eye. The distance to which these volcanic ashes are carried by the winds is truly astonishing. Barbadoes is more than twenty leagues from St. Vincent's, and Hecla is fifty leagues from Glaumba. Procopius relates, that in 472 the ashes of Vesuvius were carried as far as Constantinople; that is to say, to a distance of 250 leagues. These showers of ashes produce, in the countries where they fall, earthy beds, often of great thickness, which, on being heaped up and penetrated by water, form some kind of volcanic tuffa. See in *Blackwood's Magazine*, vol. i. p. 134—136, an excellent account, by one of our pupils, of the fall of volcanic ashes in Barbadoes.

(3.) *Volcanic sands.* These are small particles of lavas which have been ejected into the air in the form of drops, and there harden. They are nothing but very small sized scoriæ, or fragments of ordinary scoriæ. They are, moreover, mingled with numerous small

crystals of augite and felspar, or with fragments of these crystals. The quantity of these sands which volcanoes eject is immense. They form the greater part of the ejections, and of the mass of many volcanic mountains, of *Ætna* for example, according to M. Dolomieu. The finest mingle with the ashes, and form part of the clouds already mentioned. Others, accumulating in too great quantity to be sustained upon the acclivities of the mountain, slide down and spread out at its base. In the eruption in *Vesuvius* of 1822, a current of sand of this description, still red-hot, was taken at a distance for a torrent of lava.

(4.) *Scoriæ*. The gases which come from the depths of the volcano, passing through the mass of melted lava with great force and velocity, carry off some parts of that viscid matter, and bear them along with them into the atmosphere. They are there further divided, in consequence of the resistance which the air opposes to them; and, in cooling, they assume the intumesced and slaggy appearance which the *scoriæ* of forges so frequently have.

(5.) *Volcanic bombs*. When the matter of lavas is projected in a soft state, as is most commonly the case, it sometimes on cooling in the air assumes the form of drops, tears, or elongated spheroids, to which the name of *volcanic bombs* is given. They abound in the extinct volcanoes of *Auvergne*.

(6.) *Unaltered ejected masses*. Volcanoes sometimes eject stones, many of which bear no marks of common fusion. These, by some, are considered as fragments of rocks, which form the walls of internal cavities, and which may have been torn off and projected by some current of elastic fluids; others, again, maintain that they are fragments of rocks, which have been formed by igneous solution and crystallisation. Fragments of these dubious masses are found in great numbers on the *Monte Somma*. There they are of granular limestone, containing mica, and many other minerals besides.

935. *Projectile power of volcanoes*. Did our space allow of it, it would be interesting to enquire what is the intensity of that force which throws such quantities of matter to so great a height. We can only remark, that the greatest velocity in the cases of *Ætna* and *Vesuvius* was found to be equal to that of a cannon-ball at the moment when it issues from a cannon, the velocity being from four to five hundred yards per second. The gigantic *Cotopaxi* projected a piece of rock about an hundred cubic yards in magnitude to the distance of three leagues.

b. *Lavas*.

936. *Eruptions of lavas*. When we have an opportunity of seeing the liquid lava in the crater, it resembles the melted matter in our furnaces, and appears as it were boiling with greater or less violence. Jets of the melted matter are thrown up from the liquid surface, through the agency of elastic fluids. It is by these elastic fluids that the lava is raised upwards in the crater. When the mountain is high, as *Teneriffe* or *Ætna*, these fluids are not sufficiently powerful to raise the lava to the summit, or rather the sides of the mountain are not sufficiently strong to resist the weight and force of the long and heavy column of lava; it therefore presses or melts the walls which surround it, and thus forms an opening, through which it issues with great rapidity. When, on the contrary, the mountains are comparatively low, as *Vesuvius* for example, the lava reaches the mouth of the crater and flows over its lips, and from thence downwards along the acclivities of the mountain. On reaching the bottom they divide into several branches, according to the nature and slope of the ground over which they flow. The currents or streams of lava vary much in regard to the velocity with which they move. This velocity depends upon the slope of the ground upon which it flows, as well as upon the quantity and viscosity of the lava. At *Vesuvius*, M. de la Torre saw currents passing over a space of about 800 yards in an hour. Sir William Hamilton observed one which traversed 1800 yards in the same time. The eruption of 1776 presented another, which moved more than 2000 yards in 14 minutes. Buchk observed, during the eruption of 1805, a torrent flow from the summit to the sea-shore, a distance, in a straight line, of about 7000 yards. Those we have mentioned, however, are extraordinary velocities; for in general lavas move slowly. Those of *Ætna*, flowing upon an inclined plane, are considered quick when they traverse a space of 400 yards in an hour. In flat grounds they sometimes occupy whole days in advancing a few yards.

937. The *slowness* with which lavas cool is not less remarkable than that with which they move. If their surface is quickly cooled and consolidated, the case is different with the interior; the heat concentrates there, and is retained for whole years. Currents are mentioned which were flowing ten years after emerging from the crater, and lavas were seen smoking in *Ætna* twenty years after an eruption.

938. The *heat of liquid lava* is nearly that of liquid trap, as greenstone or basalt. The particular temperatures are given by Dr. Kennedy, Sir James Hall, and Professor Jameson.

939. The *magnitude* of lava currents varies much. The largest current which has ever issued from *Vesuvius* was about 14,000 yards long; that of the eruption of 1805 was 8000; that of 1794 was in length 4200 yards, in breadth from 100 to 400 yards, and in depth from eight to ten yards; that which issued from *Ætna* in 1787 was four times

larger; and Dolomieu relates that that volcano furnished one more than ten leagues in length. But the largest current known is that which in Iceland, in 1783, covered an extent of twenty leagues in length by four in breadth.

940. These *currents*, by being superinduced on each other, and having interposed between them other products of eruptions, as sand, ashes, and scorïæ, form a series of inclined beds that give rise to the cone of the mountain. In short, the cone is composed of a series of concentric layers or coats of lava, scorïæ, &c.; the outgoings of which are sometimes well seen in natural sections in the mountain.

c. *Different Kinds of Eruption.*

941. *Watery and muddy eruptions.* In the accounts of volcanic eruptions, mention is often made of torrents of water and mud vomited forth by volcanoes. Many of these watery and muddy eruptions are external actions, as is the case with those mentioned as having taken place in Vesuvius, Ætna, and Hecla; others are internal, as those of Quito.

942. (1.) *External aqueous and muddy eruptions.* These are owing to great rains, which frequently take place by the condensation of the great volumes of aqueous vapour that rise from the craters during volcanic action. This rain, on mixing with the ashes and sands, forms currents, more or less charged with earthy matters, which descend on the sides of the mountain, spread themselves at its base, and sometimes to a distance in the low country. The melting of bodies of snow by the lavas also occasions great floods of water and mud. Of this a striking instance is related as having taken place on Mount Ætna in 1755, where, by the sudden melting of a great body of snow by a stream of liquid lava, a terrible inundation was produced, which devastated the sides of the mountain for eight miles in length, and afterwards covered the lower parts of Ætna, together with the plains near the sea, with great deposits of sand, ashes, scorïæ, and fragments of lava. Similar floods of ashes and sand are mentioned by authors as taking place in Iceland and in America, where the summits reach above the snow line.

943. (2.) *Internal aqueous and muddy eruptions.* The waters also frequently make their way into the mountain by infiltration. They there collect in particular reservoirs; and at the period of explosion, or when the mountain happens to split in consequence of some shock, they issue forth, and cover the neighbouring countries. During the earthquake which overturned Lima in 1746, four volcanoes opened at Lucanos and in the mountains of Conception, and occasioned a frightful inundation. The mountains of Quito sometimes present the same phenomena; but it is there accompanied with extraordinary circumstances. The enormous cones of Cotopaxi, Pichincha, Tungouragoua, &c. are but in some measure the summits of the volcanoes to which they belong, and whose acclivities are probably encased in the great mass of the Andes. No true lavas, within the memory of man, have been vomited forth by these volcanoes; yet Humboldt saw consolidated lava currents on Sanguay, and even on Antisana. It might be said, says Humboldt, that the volcanic agents, which seldom have force sufficient to raise the column of lava to the summit of Ætna and of the Peak of Teneriffe, would still less be able to raise it in volcanoes of nearly double the height. In Ætna and Teneriffe, the lava may force an opening at the lower part of the mountains, and thus burst out; but this could not happen in volcanoes whose sides are strengthened, to a height of nearly 3000 yards, by the whole breadth of the Cordilleras. These volcanoes confine themselves to the emission of ashes, scorïæ, and pumice. They also vomit immense quantities of water and mud, but much more frequently by openings which take place on the sides of the cone than by the craters. These muddy waters form, as it were, great lakes in the different cavities which these enormous mountains contain. They issue from these cavities, as we have said, when a communication is opened with the exterior. Thus, in 1698 the volcano of Carguarazo, which is in the neighbourhood of Chimborazo, and perhaps forms a part of it, broke down, and covered with mud eighteen square leagues of country. Similar muddy waters are still contained in parts of the same country, which are of volcanic origin, but which no longer present any indication of fire; and they are equally vomited forth during great commotions of the ground. In Peru and Quito it is not by fire and currents of burning matters that the volcanoes commit their ravages, but by the water and enormous streams of mud. This substance is mud which is at first of a soft consistence, soon hardens, and bears the name of *moya*. It presents two curious phenomena. Sometimes, as in the *moya* which inundated the country of Pilielo, and which destroyed the village of that name during the earthquake of 1797, it contains a combustible matter, which renders it blackish and soiling, and which exists in so large a quantity in it that the inhabitants make use of this *moya* as a kind of fuel. Frequently the same muddy waters, issuing from subterranean caverns, carry with them a great quantity of small fishes. These fishes are a species of *pimelodes* (*P. cyclopus*). Most of them are not more than four inches long. Their number is sometimes so great that diseases are occasioned in the country by their putrefaction. They are the same as those which live in the brooks of the country. What, then, has introduced them into these subterranean

lakes? It would appear that there are some communications between the upper and lower level of these lakes and the surface of the ground ; but what could have raised them from the level of this surface to the summit of the volcanoes, for they sometimes issue from the crater? It is very difficult to give any explanation of this. From all that has been said above, it does not appear that the mud which issues from these volcanoes comes from the subterranean caverns where the volcanic fires have their focus, and prepare the matter of lava.

944. *Air and mud volcanoes.* In some countries we observe issuing from the ground jets impelled by gases and charged with earth, which, on being deposited in the form of mud, in the neighbourhood of and chiefly around the apertures which have vomited them, form cones, which represent on a very small scale volcanic cones, and which are therefore named *air volcanoes*. One of the most remarkable of these is that of Macalouba in Sicily. It consists of a hill of dried mud about 160 feet high. Its upper part, which is 2600 feet in circumference, presents a multitude of small cones of which the largest are not above a yard in diameter. They have a small crater full of soft clay, which is every instant traversed by large bubbles of gas, which burst with an exploding noise, and scatter the clay around. Some of these explosions have been seen throwing jets of mud to the height of 160 feet. In the neighbourhood of Modena there are many of these small mud volcanoes, where they are called *salses* on account of the saltiness of the water they scatter about. The gas which occasions the phenomena is hydrogen gas charged with petroleum and carbonic acid. Similar mud volcanoes occur in the Crimea, Java, Trinidad, and America.

d. *Periods of Activity of Volcanoes, and the Theory of their Formation.*

945. *Periods of activity of volcanoes.* The periods of activity of volcanoes are but transitory and of short duration. They are followed by years, or even ages, of rest. Humboldt is of opinion that the frequency of eruptions seems to be in the inverse ratio of the size of the volcano. The smallest of them, Stromboli, is continually throwing up volcanic matter ; the eruptions of Vesuvius are less frequent, there having been but eighteen recorded since 1701 ; those of *Ætna* are much rarer ; those of the Peak of Teneriffe still more so ; and the colossal summits of Cotopaxi and Tungouragoua scarcely exhibit one in the course of a hundred years. To periods of activity there sometimes succeed periods of repose. The crater is filled up and becomes covered with forests. These burning furnaces, whence torrents of fire have issued, become the reservoirs of subterranean lakes, whose waters are peopled with fishes, and in elevated situations the sides and summits of the mountains become covered with snow and ice. But most commonly the state of rest is not complete ; the crater remains open, and there is exhaled from it a greater or less quantity of vapours, which attack the masses that lie in their way. Sometimes they produce different saline and metallic incrustations. Volcanic districts in which, however, no eruption has taken place since the commencement of our history, and in which the volcanic cones are nearly effaced, still betray by their vapours and exhalations the fire which formerly ravaged them, and which is not yet extinct. Such are the *Phlegrean Fields*, on the coast of Puzzoli, in the kingdom of Naples.

946. *Cause of volcanoes.* This is an obscure subject. A conjecture, hazarded many years ago, may be stated. There being no decided proof of a central heat, in the commonly received sense, it may be assumed that the matter of lavas is seated deep in the crust of the earth, in spaces of greater or less extent, from whence it is sent up from time to time among the previously existing strata, by the agency of elastic fluids.

SECT. IV. *Earthquakes.*

947. *On earthquakes, and the changes they produce on the earth's surface.* Werner distinguishes two kinds of earthquakes. Some, he says, appear to be connected with a particular volcano, and to have their focus in the same region as it. They are only felt to the distance of a few leagues around, and their paroxysms are almost always connected with those of the volcano. Others, which appear to have their focus at a much greater depth, and whose effects are much greater, are propagated to immense distances with incredible celerity, and are felt almost at the same time at points thousands of miles distant from each other. Some of the latter however approach the former, and are still connected with volcanic phenomena. Thus, during the earthquake which overturned Lima in 1746, and which was one of the most terrible that has been recorded, four volcanoes opened in one night, and the agitation of the earth ceased.

948. *Universality of earthquakes.* If in the more violent we include the slighter agitations of the earth's surface in particular places, earthquakes may be said to be universal or general, and we may affirm that no considerable country is entirely exempted from them. Sandy deserts and fertile regions, primitive, secondary, and tertiary hills, extensive plains, and even marshy districts but little elevated above the level of the sea, afford no protection against these destructive phenomena, which are equally prevalent in cold, in temperate, and in tropical climates. They are, however, generally considered more frequent near to coasts ; thus,

Syria, the coasts and islands of Asia, America, the European coasts of the Mediterranean, and Iceland, are most subject to them; while the plains of Africa, Asia, and the North of Europe are least exposed. Viewing the whole earth, and including every slighter agitation, earthquakes appear to be exceedingly numerous, and it may be maintained that not a week passes in which the earth's surface in some place or other is not more or less agitated. The great number of concussions observed in civilised countries, and the fact that some districts are constantly agitated by them, entitles us to draw the conclusion. Their return in the places most subject to them, and in the places where they are less frequent, is not regulated by any precise period of time. Their appearance is not connected with any particular season of the year or state of the atmosphere, and they take place by day as well as by night.

949. *Phenomena of Earthquakes.* The phenomena peculiar to earthquakes are in themselves sufficiently simple. They consist in tremblings and oscillations of the earth's surface, called shocks; extending over greater or smaller tracts of country, and frequently following a particular direction. The shocks appear at first chiefly as perpendicular heavings; then as horizontal undulations or oscillations; lastly, in some instances, there is a violent agitation: the motion is more or less rotatory. If to these we add the rending, slipping, rising and sinking of the ground, the violent agitations of the sea, lakes, rivers, and springs; consisting, in springs, in their drying up or bursting forth with great violence; in lakes, rivers, and the ocean, in their falling and rising, and rushing backwards and forwards, owing to the sinking and rising of the land, we obtain an enumeration of the principal phenomena. As the subject is very interesting, we shall view it somewhat in detail, and under the following heads:—1. *Shocks.* 2. *Extent of earthquakes.* 3. *Duration of shocks.* 4. *Magnitude of rents formed, and the phenomena connected with them.* 5. *Elevation and subsidence of the land.* 6. *Agitations in the sea.* 7. *Notice of particular earthquakes.*

950. (1.) *Shocks.* The slighter shocks of an earthquake, consisting of perpendicular heavings and horizontal undulations, commonly produce rents in houses, moving light objects in them, as articles of furniture. Persons unacquainted with the phenomenon, or who do not perceive it from the subterraneous noise resembling thunder which accompanies it, feel unsteady while in their beds, but particularly when sitting, and believe themselves seized with a sudden giddiness. The shocks proceed gradually to be more violent, and then they are very easily perceived even by the inexperienced. Then the most substantial buildings are shattered to pieces, and the inhabitants buried beneath their ruins; while buildings of a lighter construction are only rent, and very slender reed huts are least of all exposed to destruction. In some cases the fracturing, or as it were trituration, surpasses description. Hence, for the plainest reasons, it is most dangerous to remain in houses or inhabited places; but even the fields and mountains themselves afford no perfect security, inasmuch as the fields frequently in some places open into fissures, and are rent asunder; while mountains are not only rent, but slide down into the valleys, dam up rivers, form lakes, and cause inundations. Although the desolation produced by these convulsions exceeds all description, this is much more the case with the rotatory motions; a species of motion, however, the existence of which has been denied by some geologists. In proof of it, however, it may be mentioned, that during the earthquake of Catania, whose general direction was from S. E. to N. W., many statues were turned round, and a large mass of rock was turned 25° from South to East. But the rotatory motion was more strikingly exemplified in the earthquake at Valparaiso, on the 19th November, 1822, by which many houses were turned round, and three palm trees were found twisted round one another like willows. These rotatory motions of masses of rock are particularly interesting when viewed in connection with phenomena connected with faults or shifts among strata in non-volcanic districts. It is only the slighter earthquakes that pass by with a single shock; in most of them more shocks follow at short intervals, and for the most part the number is proportioned to the violence of the concussion. The first shock is sometimes the most powerful, but the second is as often, if not oftener, equally violent. Further, the concussions are also repeated after longer intervals, as the earthquakes in Syria, that sometimes continue for a number of months with longer or shorter intermissions; but the first catastrophe is generally the most violent and destructive.

951. (2.) *Extent of earthquakes.* It is the agitation of the sea that points out the great extent of the tracts of land convulsed by earthquakes. In this respect, the earthquake at Lisbon, in 1755, was the most remarkable and most violent that ever visited Europe. In consequence of it, by the concussion on the bottom, or momentary rising or upheaving of the sub-marine land, the sea overflowed the coasts of Sweden, England, and Spain, and of the islands of Antigua, Barbadoes, and Martinique in America. In Barbadoes the tide, which rises only 28 inches, rose 20 feet in the bay of Carlisle, and the water appeared as black as ink, owing probably to bituminous matter thrown up from the bed of the ocean. On the 1st of November, when the concussion was most violent, the water at Guadaloupe retreated twice, and on its return rose in the channel of the island to a height of from 10 to 12 feet. Similar appearances were witnessed at Martinique. A wave of the sea, 60 feet high, overflowed a part of the city of Cadiz; and the lakes of Switzerland, such as Geneva, were observed to be in commotion six hours after the first shock. It is also remarkable that agitations were

noticed in lake Ontario, in October, 1755. During the earthquake at Lima, 1586, a wave of the sea rose 84 feet high in the harbour of Callao. During the earthquakes in Calabria in 1783, the sea not only overflowed the coast and drowned many people, but was in general so much agitated that the guns on ship-board sprang from the deck to a height of several inches.

952. (3.) *Slipping of Mountains.* Besides the common operations of earthquakes already mentioned, others occur that do not immediately succeed the concussions, and therefore happen less frequently. To these belong the sliding down of parts of mountains, as at Dobratch in 1345, and the falling together of two mountains in Jamaica in 1692, by which the bed of a river was dammed up. In the latter place, a part of a mountain slid down and covered many plantations; the city of Port Royal sunk to the depth of eight fathoms; and a plain of 1000 acres fell in, with all the buildings upon it.

953. (4.) *Duration of shocks.* Single shocks frequently succeed one another very rapidly, and often after greater or smaller intervals of time; they are occasionally single, frequently very numerous; and in volcanic districts, shocks sometimes happen after a lapse of months or years, are then followed by longer or shorter intervals, and even periods of 10 or a 100 years. In regard to this, it is remarkable that since the earthquake which in 1204 shook Antioch, Damascus, and Tripoli, Syria was spared till the latter half of the seventeenth century, although no region of the earth suffers more from these destructive phenomena than that country. It is, in short, difficult to define the duration of a single shock. It is undoubtedly brief in general; and in slighter shocks, witnessed by tranquil spectators and consequently observed with greater attention, it is not longer than a few seconds. In the greater convulsions, for instance at Lima, Caraccas, Calabria, Catania, Zante, Antioch, &c. the time is reckoned from fifty seconds to one minute and five seconds, or indefinitely from a few minutes to a few seconds. When we consider how exceedingly distracted the attention is when the shock is first perceived, the duration cannot be measured by means of a watch, but by supposition, and by such a mode of computation we are in the habit of reckoning time much longer than it really is, so we may with great probability conclude that the duration of a single shock does not go beyond a few seconds, and we may affirm that, at the most, it rarely exceeds half a minute.

954. (5.) *Magnitude of rents formed by earthquakes.* These vary from a few feet to many fathoms in extent. They have either a direction which is nearly straight or more or less winding, or they run in all directions from a centre. During the terrible Calabrian earthquakes of 1783, rents were formed of great dimensions; in the territory of San Fili there was formed a rent half a mile long, two feet and a half broad, and twenty-five feet deep; in the district of Plaisano, a rent, of nearly a mile in length, one hundred and five feet broad, and thirty feet deep opened; and in the same district two gulfs arose, one at Cerzulli, three quarters of a mile long, one hundred and fifty feet broad, and about one hundred feet deep; and another, nearly a quarter of a mile long, about thirty feet broad, and two hundred and twenty-five feet deep. Ulloa relates that in the earthquake of 1746, in Peru, a rent took place, which was two miles and a half long, and four or five feet wide. These rents sometimes close again; thus, in the year 1692, in the island of Jamaica, during an earthquake, the ground heaved like a boiling sea, and was traversed by numerous rents, two or three hundred of which were often seen at a time opening and closing rapidly again.

955. (6.) *Elevation and subsidence of land during earthquakes.* It is evident that if the land is fractured and then traversed with vast rents, by earthquakes, that portion of the land will in some places sink and in others rise, and this not once but several times in the same place. In the year 1772, during an eruption of one of the loftiest mountains in Java, the ground began to sink, and a great part of the volcano, and part of the neighbouring country, estimated to be fifteen miles long and six miles broad, was swallowed up. During the earthquake at Lisbon in 1755, a new quay entirely disappeared; thousands of the inhabitants had taken shelter on it, to be out of the reach of the tottering and falling buildings, when suddenly the quay sunk down with its thousands of human beings, and not one of their dead bodies ever floated to the surface. In the year 1692, during an earthquake in Jamaica, a tract of land about a thousand acres in extent sank down in less than a minute, and the sea immediately took its place. On the north side of the island several large tracts with their whole population were swallowed up, and a lake appeared in their place covering above a thousand acres. Numerous examples of the upraising of the land by earthquakes might be given; we shall enumerate a few of them. On the 19th of November, 1822, a most dreadful earthquake visited the coast of Chili; the shock was felt at the same time throughout a space of one thousand two hundred miles from north to south. When the country around Valparaiso was examined on the morning after the shock, it was found that the entire line of coast, for the distance of more than a hundred miles, was raised above its former level. The area over which this upraising took place was estimated at one hundred thousand square miles: the rise upon the coast was from two to four feet; at the distance of a mile inland, it was estimated from five to seven feet. On the 18th of March in the year 1790, at St. Maria di Niscomi, some miles from Terranuovo, near the south coast of Sicily, a loud subterranean

noise was heard under the town just mentioned, and the day after earthquakes were felt; then the ground gradually sunk down for a circumference of three Italian miles, during seven shocks, and in one place to a depth of thirty feet; as the subsidence was unequal, rents were formed, some of which were so wide that they could not be leaped over: this gradual sinking continued to the end of the month. About the middle of this period an opening took place in the subsiding land, about three feet in diameter; through these continued to flow, for three hours, a stream of mud, which covered a space sixty feet long and thirty feet broad; the mud was saltish and composed of chalky marl and a viscid clay, with fragments of crystalline limestone; it smelt of sulphur and petroleum. On the 16th June, 1819, at Cutch in Bombay, a violent earthquake took place, during which, independent of other changes, the eastern and almost abandoned channel of the Indus was much altered: this estuary was, before the earthquake, fordable at Luckput, being only a foot deep when the tide was at ebb, and at flood tide never more than six feet; but it was deepened at the fort of Luckput, after the earthquake, to more than eighteen feet at low water, showing that a considerable depression had taken place. The channel of the river Runn was so much sunk that, instead of being dry as before, during that period of the year, it was no longer fordable except at one place; and it is remarked by Captain Macmurdoch, — and the observation is of high geological import, as connected with the formation of valleys, of river districts, &c. — “should the water continue throughout the year, we may perhaps see an inland navigation along the northern shore of Cutch; which, from stone anchors, &c. still to be seen, and the tradition of the country, I believe to have existed at some former period.” Sindree, a small mud fort and village belonging to the Cutch government, situated where the Runn joins the Indus, was overflowed at the time of the shock. The people escaped with difficulty, and the tops of the houses and walls are now alone seen above water. In the year 1790, in the Caraccas, during an earthquake, a portion of granite soil sunk, and left a lake 800 yards in diameter, and from eighty to an hundred feet deep: it was a part of the forest of Aripao which sunk, and the trees remained green for several months under water.

956. (7.) *Agitations of the sea.* We have already noticed, in a general way, the agitations observed in the sea during earthquakes; we shall now add some particulars illustrative of these motions. During the Lisbon earthquake of 1755, the sea rose along the coast of Spain; and at Cadiz it advanced in the form of vast waves sixty feet high. At Lisbon about sixty thousand persons perished. The sea first retired, and laid the bar dry; it then rushed in, rising upwards of fifty feet above its ordinary level. At Kinsale, in Ireland, the sea rushed into the harbour, and invaded the land. At Tangier, in Africa, it rose and fell eighteen times on the coast. At Funchal, in Madeira, it rose fifteen feet above high-water mark; although the tide, which ebbs and flows there seven feet, was then half-ebb. Even ships at sea, a considerable distance from land, felt, in the midst of these convulsive motions, as if hurried across a ridge of rocks. This took place, to a distance of 160 or 270 nautical miles from the coast, during the earthquake at Lisbon in 1816. During the Lisbon earthquake of 1765, the shock was felt at sea, on the deck of a ship to the west of Lisbon, and produced nearly the same feeling as on land. At San Lucar, the captain of the Nancy frigate felt his ship so violently agitated that he thought he had struck on the ground; but, on heaving the lead, found he was in deep water. Captain Clark, from Derina, in N. lat. $36^{\circ} 24'$, between nine and ten in the morning, had his ship shaken as if she had struck upon a rock, so that the seams of the deck opened. Dr. Shaw relates, that in 1724, being on board the Gazello, an Algerine ship of 50 guns, they felt such violent shocks, one after another, as if the weight of twenty or thirty tons had been let fall from a good height on the ballast. Schouten, speaking of an earthquake which happened in the Moluccas, says, that the mountains were shaken, and ships that were at anchor in thirty or forty fathoms' water were jerked as if they had run ashore, or come foul of rocks. Le Genil says, “that ships at sea and at anchor suffer, during earthquakes, such violent agitations that they seem to be falling asunder; their guns break loose, and their masts spring.”

957. (8.) *Notices of particular Earthquakes.* A full account of all the principal earthquakes that are known would much exceed our limits; we shall, therefore, select only a few of the more interesting.

958. *No part of Europe is more visited by earthquakes than Italy and the neighbouring islands.* The first earthquake particularly worthy of notice was that which, in the year 63, destroyed Herculaneum and Pompeii. Since that period they have frequently visited Italy and Sicily, but much seldomer from A. D. 63 to the twelfth century, than from that period till modern times, that is, till the eighteenth and nineteenth centuries. Of these we shall describe one of the most recent in Calabria, and another of still later date in Sicily.

959. *Earthquake of 1783.* The earthquake that so much affected Calabria, and destroyed the city of Messina, raged at unequal periods from the 5th of February till the 28th of March, 1783. According to Sorcia, its principal seat was the small town of Oppido in the neighbourhood of Atramonte, a snow-covered peak of the Apennines.

From this point, says Sir William Hamilton, around to a distance of twenty-five miles, comprehends the surface of country which suffered most, and where all the towns and villages were destroyed. If we describe the circle with a radius of seventy-two miles, it will include the whole country which was in any way affected by the earthquake. The first shock, on the 5th February, in two minutes threw down the greatest part of the houses in all the cities, towns, and villages from the Western acclivities of the Apennines, in Calabria Ultra, to Messina in Sicily, and convulsed the whole surface of the country. Another shock, which took place on the 25th of March, was nearly equally violent. The granite chain which extends through Calabria from north to south was but slightly agitated, the principal shocks being propagated with a wave-like motion through the tertiary sands, sandstones, and clays, from west to east. It was remarked that the violence of the shock was greatest at the line of junction of the granite and tertiary rocks, occasioned probably by the interruption of the undulatory movement of the softer strata by the harder granite. The granite range also prevented the passage of the shocks to the countries on the opposite side of the mountain-range. About 200 towns and villages were destroyed, more than one hundred hills slid down, fell together, dammed up rivers, and formed lakes: numerous rents, often of vast magnitude, were formed; many subsidences and also upraisings of the ground took place; and the general features of the country were so much changed that they could scarcely be recognised. Thus, in a very short space of time the whole country was as much changed as if it had been exposed to common influences for many thousand years. The total number of human beings that perished was estimated at 100,000, and it was difficult to find even distant relations to succeed to the property of some families.

960. *Earthquake of Lisbon in 1755.* In no part of southern Europe has so tremendous an earthquake occurred as that which began on the 1st of November, 1755. On the morning of that day, at thirty-five minutes after nine, without the least warning, except a noise like thunder heard under ground, a most dreadful earthquake shook, by short but quick vibrations, the foundations of Lisbon, so that many of the principal edifices fell to the ground in an instant: then, with a scarcely perceptible pause, the nature of the motion changed, now resembling that of a waggon driven violently over rough stones, which laid in ruins almost every house, church, convent, and public building, with an incredible destruction of the people. It continued in all about six minutes. At the moment of its beginning, some persons on the Tagus, near a mile from the city, heard their boat make a noise as if it had run aground, though then in deep water, and saw at the same time houses falling on both sides of the river. Four or five minutes after, the boat made the like noise, caused by another shock, which brought down more houses. The bed of the Tagus was in many places *raised to its surface*. Ships were driven from their anchors, and jostled together with great violence; and the masters did not know if they were afloat or aground. The large quay called *Cays de Prada*, was overturned, crowded with people, and sunk to an unfathomable depth in the water, not so much as one body afterwards appearing. *The bar was seen dry from shore to shore*; then suddenly the sea, like a mountain, came rolling in, and about Belem castle the water rose fifty feet almost in an instant; and had it not been for the great bay opposite the city, which received and spread the great flux, the lower part must have been under water. As it was, it came up to the houses, and drove the inhabitants to the hills. About noon, there was another shock, *when the walls of several houses which were yet standing were seen to open from top to bottom more than a quarter of a yard, but closed again so exactly as to leave scarce any mark of injury*. It is remarked, that on the 1st of November, 1756, being the anniversary of the fatal tragedy of this unhappy city, another shock gave the inhabitants so terrible an alarm that they were preparing for their flight into the country, but were prevented by several regiments of horse placed all around by the king's orders. Many of the largest mountains in Portugal during the great earthquake were shaken as it were to their foundation, and many of them opened at their summits, split, and rent, and huge masses of them were cast down into the subjacent valleys. The same dreadful visitation was experienced at Oporto. We are told that at about forty minutes past nine in the morning, the sky being serene, was heard a dreadful hollow noise like thunder or the rattling of coaches over rugged stones at a distance; and almost at the same instant was felt a severe shock of an earthquake, which lasted six or seven minutes, during which every thing shook and rattled. It rent several churches. *In the streets the earth was seen to heave under the people's feet, as if in labour*. The river was also amazingly affected; for in the space of a minute or two, it rose and fell five or six feet, and continued to do so for four hours. The river Douro was observed to burst open in some parts, and discharge vast quantities of air; and the agitation was so great in the sea, beyond the bar, that it was imagined the air got vent there also.

961. *On the fatal day of the great earthquake of Lisbon, at Ayamonte*, near where the Guadiana falls into the bay of Cadiz, a little before ten o'clock, immediately on a rushing noise being heard, a terrible earthquake was felt, which during fourteen or fifteen minutes damaged almost all the buildings. In little more than half an hour after, the sea and

river, with all their canals, overflowed their bounds with great violence, laying under water all the coasts of the islands adjacent to the city and its neighbourhood, flowing into the streets. The water rose three times, after it had as many times subsided. One of the swells was at the time of ebb. The water came on in vast black mountains, white with foam at the top, and demolished more than half of the town at the bar called De Canala. The earth was observed to open in several places, and from the apertures flowed vast quantities of water.

962. *At Cadiz*, in the same morning, some minutes after nine, the whole town was shaken with a violent earthquake, which lasted about five minutes. The water in the cisterns under ground rolled backwards and forwards. At ten minutes after eleven, a wave was seen coming from sea, eight miles off, at least sixty feet higher than usual. It dashed against the west part of the city; at last it came upon the walls, beat in the breast-work, and carried pieces of eight or ten tons weight forty or fifty yards from the wall. When the wave was gone, some parts that are deep at low water were left quite dry, for the water returned there with the same violence as it came. On the same eventful morning Gibraltar was agitated by an earthquake. It lasted about two minutes. *The guns on the battery were seen to rise, others to sink, the earth having an undulating motion.* Most people were seized with giddiness and sickness, and some fell down, others were stupefied, though many that were walking or riding felt no motion, but were sick. The sea rose six feet every fifteen minutes, and fell so low that boats and all the small craft near the shore were left aground, as were numbers of fish. Ships in the bay thought they had struck on rocks. The flux and reflux lasted till six next morning, having decreased gradually from two in the afternoon.

963. *This earthquake excited much attention*, from the incredibly great extent at which slighter contemporary shocks were experienced. They extended from Greenland and Iceland to Norway, Sweden, Germany, Britain, Switzerland, France, Spain, Morocco, Salee, Fez, Teutan, and even to the West Indies and the lake Ontario in North America.

964. *However dreadful many of the earthquakes of Europe were*, they bear no comparison with those which have desolated many parts of Asia. Passing over those which were observed in the islands, on the eastern continent, and in the environs of the Caspian Sea, our attention is particularly drawn towards Syria, on account of the ravages it has frequently experienced.

965. *Gibbon*, in the forty-third chapter of his *Decline and Fall of the Roman Empire*, gives the following account of the earthquake that took place at Antioch in A. D. 526, May 30. "The near approach of a comet may injure or destroy the globe which we inhabit; but the changes on its surface have been hitherto produced by the action of volcanoes and earthquakes. The nature of the soil may indicate the countries most exposed to these formidable concussions, since they are caused by subterraneous fires, and such fires are kindled by the union and fermentation of iron and sulphur. But their times and effects appear to lie beyond the reach of human curiosity, and the philosopher will discreetly abstain from the prediction of earthquakes, till he has counted the drops of water that silently filtrate on the inflammable mineral, and measured the caverns which increase by resistance the explosion of the imprisoned air. Without assigning the cause, history will distinguish the periods in which these calamitous events have been rare or frequent, and will observe, that this fever of the earth raged with uncommon violence during the reign of Justinian. Each year is marked by the repetition of earthquakes, of such duration, that Constantinople has been shaken above forty days; of such extent, that the shock has been communicated to the whole surface of the globe, or at least of the Roman empire. An impulsive or vibratory motion was felt: enormous chasms were opened, huge and heavy bodies were discharged into the air, the sea alternately advanced and retreated beyond its ordinary bounds, and a mountain was torn from Libanus, and cast into the waves, where it protected, as a mole, the new harbour of Botrys, in Phœnicia. The stroke that agitates an ant-hill, may crush the insect myriads in the dust; yet truth must extort a confession, that man has industriously laboured for his own destruction. The institution of great cities, which include a nation within the limits of a wall, almost realises the wish of Caligula, that the Roman people had but one neck. *Two hundred and fifty thousand persons* are said to have perished in the earthquake of Antioch, whose domestic multitudes were swelled by the conflux of strangers to the festival of the Ascension. The loss of Berytus was of smaller account, but of much greater value. That city, on the coast of Phœnicia, was illustrated by the study of the civil law, which opened the surest road to wealth and dignity: the schools of Berytus were filled with the rising spirits of the age, and many a youth was lost in the earthquake who might have lived to be the scourge or the guardian of his country. In these disasters, the architect becomes the enemy of mankind. The hut of a savage, or the tent of an Arab, may be thrown down without injury to the inhabitants; and the Peruvians had reason to deride the folly of their Spanish conquerors, who with so much cost and labour erected their own sepulchres. The rich marbles of a patrician are dashed on his own head; a whole people is buried under the ruins of public and private edifices, and the conflagration is kindled and propagated by the innu-

merable fires which are necessary for the subsistence and manufactures of a great city. Instead of the mutual sympathy which might comfort and assist the distressed, they dreadfully experience the vices and passions which are released from the fear of punishment: the tottering houses are pillaged by intrepid avarice; revenge embraces the moment, and selects the victim; and the earth often swallows the assassin or the ravisher in the consummation of their crimes. Superstition involves the present danger with invisible terrors; and if the image of death may sometimes be subservient to the virtue or repentance of individuals, an affrighted people is more forcibly moved to expect the end of the world, or to deprecate with servile homage the wrath of an avenging Deity." In 1169 single shocks continued for four months; and in 1202 another earthquake destroyed many cities, filled up the valleys of Lebanon, and shattered the basaltic districts of Hauran, so that, according to the expression then current, *it was no longer possible to say, Here stood this or that city.* A dreadful earthquake took place in 1759; the shocks continued for six months. At the first shock the cities of Antioch, Balbec, Acre, Tripoli, &c. were laid in ruins, and 30,000 persons killed. The most recent earthquake, of 1822, lasted still longer, and committed dreadful ravages. On the 13th of August, in one horrible night, Aleppo, Antioch, Biha, Gesser, indeed every single village and cottage within the pashalic of Aleppo, was, within ten or twelve seconds, completely destroyed, and converted into a heap of rubbish: no less than 20,000 people lost their lives, and many more were mutilated; a very great number, considering the low population of these places.

966. *Africa* is very little known, and we are therefore ignorant of any earthquakes in its interior, where they may occur as frequently as in other places. The southern extremity of this continent is rarely visited by slight shocks, but they are more numerous in the north, where, in March, 1825, they did considerable damage to Algiers and Blida. On the contrary, *America*, particularly in the southern parts, is inferior to no part of the world for the magnitude, number, and duration of its earthquakes. We shall now mention a few of the greatest recorded by naturalists. To these belong the earthquake of 1746, which, within five minutes, destroyed the greater part of Lima; Callao was inundated; and of 4000 persons, 200 only escaped. The destruction of New Andalusia, on the 21st of October, 1766, was equally terrible. The shocks extended over Cumana, Caraccas, Maracaibo, the shores of the Casanar, the Meta, the Orinoco, and Ventures; and the granite districts in the mission of Encaranada were also shaken by their violence. An earthquake, in 1797, destroyed a great part of Peru. It proceeded from the volcano Tungouragoue, continued with slight shocks during the whole of February and March, and returned on the 15th of April, with increased violence. Many places were filled up by the summits of mountains tumbling down; muddy water flowed from the volcano; and, spreading over the country, became afterwards an indurated crust of clay. The entire number of persons who perished on this occasion was 16,000. No earthquake could well be more destructive to any place than that which destroyed the Caraccas in 1812, and of which Humboldt has given an excellent description. The Caraccas was thought secure on account of its primitive mountains, although in 1641, 1703, and 1778, violent earthquakes were experienced, and a slighter shock in 1802. Humboldt, from actual inspection, had no doubt but this country, from being in a volcanic region, must be liable to such disasters. In December, 1811, various shocks were felt; on the 12th of March, 1812, the city of Caraccas was destroyed. The sky was clear, and in Venezuela there had not been a drop of rain for five months, there was no forewarning prognostic, for the first shock at seven minutes past four in the afternoon came on unexpectedly, and set the bells a-ringing. This was immediately succeeded by a second shock, which caused a waving and rolling motion in the earth, then a subterraneous rumbling noise was heard, and there was a third shock, in which the motion was perpendicular and sometimes rolling horizontally, with a violence which nothing could withstand. The people, in place of flying directly to the open fields, flocked in crowds to the churches, where arrangements had been made for a procession; and the multitudes assembled there were buried beneath the ruins. Two churches 150 feet high, and supported by columns of from twelve to fifteen feet in diameter, fell in a mass of rubbish, and were for the most part ground into dust. The Caserne el Quartel vanished almost entirely, and a regiment of soldiers stationed there, and about to join the procession, disappeared at the same time along with it; a few individuals only escaped; nine tenths of the city were completely destroyed, and most of the houses that remained were rendered uninhabitable; the number of people killed was reckoned at nearly 10,000, without including those who perished afterwards from bruises and want of sustenance. The clouds of dust having fallen, were succeeded by a serene night, which formed a frightful contrast with the destruction on the earth, and with the dead bodies lying scattered among the ruins. The duration of each particular shock was reckoned by some 50 seconds, by others 1 minute 12 seconds. These shocks extended over the provinces of Venezuela, Varinas, Maracaibo, and into the mountains in the interior. La Guyara, Mayquatia, La Vega, St. Felipe and Merida, were almost entirely destroyed. In Guyara and St. Felipe the number of persons killed was about 5000. On the 5th of April another violent earthquake took place, during which enormous fragments were detached from the

mountains. It was said that the mountain Silla lost from 350 to 360 feet of its height by sinking.

967. *Cause of earthquakes.* — The original hypothesis, which attributed volcanic eruptions and earthquakes to the operation of central fire, was at first attacked chiefly by Stukely, who, from the phenomena of two earthquakes observed at London on the 8th February and 8th of March, 1749, endeavoured to prove that they were caused by a highly over-charged state of the electric fluid. Andrew Bena affirms, that they are sudden explosions, caused by gas in the interior of the earth, which he believes would be found there enclosed in reservoirs of sulphur and bitumen. Beccaria, as is known, endeavoured to attribute to electricity every thing that had any probable affinity for it; hence he believed that an accumulation of it in the crust of the earth produced concussions with the clouds, and then exhibited the appearance of earthquakes. Humboldt found it to be a prevailing opinion in America that earthquakes are electrical phenomena; but observes, that this must be excused by reason of the partiality entertained for Franklin. The invention of the Voltaic pile, and the observation of its singular operations, induced many philosophers, at least those naturalists who were perfectly intimate with the nature of this remarkable apparatus, to consider the whole earth as a column or pile of this description, or that it contains an apparatus of this description in its interior. These fancies, however, lead to nothing satisfactory. Where then can we seek for the cause or causes of earthquakes? The subject is entirely hypothetical, as we have no means of reaching the seat of these remarkable phenomena. The theory of the earthquake is the same as that of the volcano. The agitations may be produced by the motions of the liquid and gaseous matter at a great depth in the crust of the earth endeavouring to escape.

SECT. V. *Account of the different Structures observable in the Crust of the Earth.*

968. *Before the time of Werner*, little had been accomplished in regard to the determination of the structures that occur in the crust of the earth. Some maintained that every where irregularity prevailed, and that it was in vain to look for order or regularity in the coarse rocky masses of which mountains, hills, and plains are composed. Werner, however, on general grounds, assumed, that if determinate structures and arrangements occurred in the vegetable and animal kingdoms, the same must be the case in the mineral kingdom, not only in simple minerals, but also in the great and more generally distributed masses of which the crust of the earth is principally composed. His investigations fully confirmed the truth of this opinion, for minerals he found as well characterised as plants and animals; and the following details will show that there exists among *mountain rocks*, or those great masses of which the crust of the earth is composed, a beautiful series of structure, from that of *hand specimens* to the general arrangements of the great rock formations. We shall consider these structures in the following order, beginning with the smallest and terminating with the greatest.

SUBSECT. 1. *Different Structures.*

1. Structure of mountain rocks in hand-specimens.
2. Structure of strata and beds.
3. Structure of formations.
4. Arrangements of formations in regard to each other.
5. Structure of veins.

969. (1.) *Structure of mountain rocks.* The kinds of structure occurring in mountain rocks are the following: — 1. Compact. 2. Slaty. 3. Granular. 4. Porphyritic. 5. Amygdaloidal. 6. Conglomerated. In the *compact structure*, the mass is uniform, without slaty or any other arrangement, and when broken exhibits various fractures, as earthy, splintery, conchoidal, even, &c. Common compact quartz is an example of this kind of structure. In the *slaty structure* the rocks split readily into thin layers or slates, as in common roofing-slate. Rocks having the *granular structure* are composed of granular concretions or imperfect crystals, as in primitive limestone or statuary marble. In the *porphyritic structure* there is a basis or ground with imbedded crystals, generally of felspar or quartz, or both, as in porphyry: in the *amygdaloidal structure* there is also a basis or ground; but here the base does not contain imbedded crystals, but amygdaloidal cavities, which are either nearly empty, half filled, or completely filled with minerals. The rock named amygdaloid exhibits this kind of structure. Lastly, the *conglomerated structure* is that which we observe in the rock named conglomerate, which is composed of fragments imbedded in a basis or ground.

970. (2.) *Structure of strata and beds.* When a mountain or hill is composed of tabular masses of the same kind of rock, as of sandstone, that extend throughout the hill, it is said to be stratified, and the individual tabular masses are named *strata*, as in *fig. 58*. If among these strata there occur tabular masses of a different rock, the masses are named *beds*: *a*, *fig. 58*.

represents a bed of limestone in the cliff of stratified sandstone. These strata and beds vary

in position; sometimes they are flat or *horizontal*, or they are more or less inclined until they become *vertical*, or are set on their edges. They also vary in the point of the compass towards which they are *inclined* or *dip*; but it is worthy of remark, that the dip is always at right angles to the range or direction of the strata; and that if the dip is given, we know the direction: but a knowledge of the direction will not give us the dip. Their *direction* also varies. In this country the primitive and transition rocks often range or have their direction from N.E. to S.W. The position of strata is determined by a well known instrument, the clinometer, which is a compass with an attached quadrant. When we examine the structure of individual strata and beds, several varieties may be discovered: thus, in some beds, the rock is arranged in *columns*, as in basalt; in others, the arrangement is in *tables*, as in porphyry; or in *balls*, as in granite and greenstone.

971. (3.) *Structure of formations.* The idea of formations was first clearly brought out by Werner. To his views on this most important subject we can trace the new character of geology, and the great progress made in geognosy within these last thirty years. But this is not the place for discussing the subject. All those rocks which appear to have been formed at the same time, and in the same or similar circumstances, and which agree in position, structure, mass, petrifications, imbedded minerals, &c. are said to belong to the same formation. These formations are divided into *simple* and *compound*. *Simple formations* are those principally composed of one rock; *compound formations*, of more than one species of rock: granite is an example of a simple formation; the first secondary sandstone, or the great coal formation, of a compound formation, because it contains several rocks; viz. sandstone, slate, limestone, coal, and ironstone.

972. (4.) *Arrangement of formations in regard to each other.* When two formations occur together, and the one rests upon the other, the subjacent formation is named the *fundamental rock*, and that which covers or lies upon the other, the *superincumbent*. The line where the two rocks or formations meet is called the *line of separation* or *line of junction*. In fig. 59. *a* is the fundamental rock, and *b* the superimposed rock, and *c c* the line of junction.

When the strata of the superimposed formation is parallel with the strata of the fundamental or subjacent rock, the stratification is said to be *conformable*, as fig. 60., where a formation *a*,

we shall say of limestone, rests on *b*, of sandstone. If the strata of the superimposed formation are disposed as at *c*, fig. 61., they are said to be *unconformable*. Lastly, if the

strata lie over the ends of the strata of the fundamental rock, as at *b*, in *fig. 59.*, they are said to be *unconformable* and *overlying*. If the strata rest on the fundamental rock, as represented

in *fig. 62.*, they are said to be *saddle-shaped*; if as represented in *fig. 63.*, they are said to

be *mantle-shaped*; if disposed in a basin-shaped hollow, as in *fig. 64.*, they are said to be

basin-shaped; if in a lengthened or trough-like hollow, as in *fig. 65.*, they are said to be

trough-shaped. In a mountain, or natural section of Neptunian or aquatic rocks, as limestone, sandstone, slate, &c., the undermost or lowest-lying strata are considered to be the oldest; therefore, on ascending a mountain, as that in *fig. 66.*, from *a* to *b*, we pass from

the newer to the older rocks; but if from *c* to *b*, from the older to the newer. Formations were formerly more continuous than at present, portions only remaining of extensive deposits. The remaining portions occupying different situations have received particular names, according to the situations in which they occur. When in patches on the summits of hills, as represented at *a a a* in *fig. 67.*, they are called *mountain-caps*. When in hollows, as at *b b*, they are named *upfillings*.

973. (5.) *Structure of veins.* These are tabular masses that intersect the strata and beds of the mountain or tract in which they occur. The tabular masses of trap or whinstone veins that cut across the strata of this country are popularly known under the name *whin dykes*. Veins, like strata, vary in position, being sometimes vertical, at other times not much inclined to the horizon; their direction, inclination, and dip are determined in the same manner as in strata. These intersecting masses vary in *breadth* from an inch or less to many fathoms; in *length*, from a few inches to several miles; and in *depth*, from a few inches to an unknown

and vast depth. Veins appear to have been originally open rents or fissures traversing the strata, which have been filled by an after-process with the mineral matters they now contain.

68

This being the case, we naturally expect to find the strata on the walls of veins exhibiting the same phenomena as occur in the walls of rents. When rents cut across strata, they sometimes, as in *fig. 68.*, at *a, b*, produce no derangement; while, in other cases, the strata on the opposite sides of the rent do not correspond, owing to the strata on one side sinking down, as represented in *fig. 69.*: this derangement is called a *shift, slip, or fault.*

69

Such, then, are the different structures observable in the great masses of which the crust of the earth is composed. We next proceed to give —

SECT. VI. *An Account of the different Classes and Species of Rocks of which the Crust of the Earth is composed.*

974. It was at one time a general opinion that the formations of which the crust of the earth is composed were destitute of all regularity in distribution and in individual characters. Lehman, a German miner, was early convinced of a certain degree of order in their arrangement; and in his well known work, first stated their division into *Primitive* and *Secondary*; under the first including those destitute of fossil organic remains, while under the other he arranged all those containing petrifications or fossil organic remains. The first, he said, were generally in highly inclined strata, the other in horizontal strata. Werner first distinctly characterised these two classes of rocks, and added to them other two classes, viz. the *Transition* and *Local*, or what are now called *Tertiary*. The whole rocks, from the oldest to the newest, were arranged by Werner under the following names and in the following order: — 1. Primitive. 2. Transition. 3. Secondary. 4. Local, the Tertiary of the present geology. 5. Alluvial. 6. Volcanic. This arrangement, more or less modified, still remains, being adopted by the principal geologists in Europe and America.

975. *Primitive rocks.* The rocks of this class lie under those of the succeeding classes. Countries in which they predominate are in general more rugged and lofty than those composed of rocks of the other classes; further, their cliffs are more extensive, their valleys narrower and deeper, and more uneven, than those in secondary countries. The strata of primitive mountains are very frequently highly inclined; a circumstance which contributes in an especial manner to the increase of the ruggedness and inequalities of the surface of primitive regions. The primitive strata in many countries maintain a wonderful uniformity of direction. Thus, in Scotland the general direction of the strata of primitive mountains is from N. E. to S. W.; and the same is nearly the case in the vast alpine regions of Norway, and in many of the lofty and widely extended primitive lands of other parts in Europe. The rocks of which primitive mountains and plains are composed are throughout of a crystalline nature, and present such characters as intimate their formation from a state of solution. These characters are the intermixture of the concretions of which these are composed at their line of junction, their mutual penetration of each other, their considerable lustre, pure colours, and translucency. Thus, in granite the concretions of felspar, quartz, and mica are joined together without any basis or ground; and at their line of juncture are either closely attached together, or are intermixed; and frequently branches of the one concretion shoot into the other, thus occasioning a mutual interlacement, as is observed in bodies that have been formed simultaneously and from a state of solution. These characters show that the concretions of granite (and the same applies to the concretions of limestone, gneiss, mica slate, and other rocks of the primitive class,) are of a crystalline nature, and have been formed at the same time. The strata are so arranged as to show that they are

crystalline formations. Primitive rocks contain no organic remains, hence are inferred to have been formed before animals and vegetables were called into existence. Primitive rocks abound very much in metalliferous minerals, and hitherto no metal has been met with which does not occur, either exclusively or occasionally, in this class of rocks. Tin, wolfram, and molybdena occur more frequently in these rocks than in other situations. Gold, silver, lead, copper, iron, cobalt, zinc, manganese, arsenic, and mercury, occur either disseminated, in beds, veins, or imbedded on various rocks of this class, and many primitive districts are characterised by the metalliferous deposits they contain.

976. *The most beautiful of all the productions of the mineral kingdom*, the gems, occur in great variety in primitive rocks. Nothing can be more beautiful than the *drussy cavities* met with in primitive mountains, whose walls are lined with pure and variously tinted and crystallised topaz, beryl, rock crystal, fluor spar, and calcareous spar; the gneiss, granite, and mica slate, with their *imbedded* crystals and grains of sapphire, chrysolite, and garnet; and the *veins* in granite, clay slate, and other primitive rocks, with their emeralds, axinites, and spinel rubies, afford to the mineralogist highly interesting combinations.

977. *Species of primitive rocks.* — The following are the species of rocks that form the primitive parts of the crust of the earth: — 1. Granite. 2. Syenite. 3. Protogine. 4. Trap. 5. Serpentine. 6. Porphyry. 7. Gneiss. 8. Mica slate. 9. Clay slate. 10. Quartz rock. 11. Limestone.

978. *Of these rocks one set*, consisting of certain granites, with trap, gneiss, mica slate, clay slate, quartz rock, and limestone, are said to be of *Neptunian* origin, that is, have been deposited from a liquid, probably water; the other set, including certain granites, with syenite, porphyry, protogine, serpentine and diallage rock, are named *Plutonic* or *igneous*, it being probable that they have been formed from a state of igneous solution. We shall describe first the Neptunian, and next the Plutonian primitive rocks.

SUBJECT. 1. *Neptunian Primitive Rocks.*

979. (1.) *Granite* is a granular compound of felspar, quartz, and mica. It occurs in beds and in imbedded masses, and also in included veins in gneiss, mica slate, and clay slate. From its intimate connection with these rocks, it is inferred to be a Neptunian deposit.

980. (2.) *Trap*. Under this name we include all those granular primitive rocks in which hornblende is the sole or predominant constituent part. These rocks sometimes appear arranged like the steps of a stair; hence the name trap, from the Swedish word *trappa*, a stair.

981. (3.) *Gneiss* is a granular slaty compound of felspar, mica, and quartz.

982. (4.) *Mica slate* is a slaty compound of mica and quartz. *Talc slate* and *micaceous talc rocks* may be arranged under this head.

983. (5.) *Clay slate* is a slaty rock, frequently entirely composed of minute scales of mica.

984. (6.) *Quartz rock*. This rock is almost entirely composed of quartz, either in granular concretions or in the compact form; and grains of felspar and scales of mica not unfrequently occur in it. When the felspar increases in quantity, the compound at length passes into granite. When the scales of mica increase and the felspar disappears, mica slate is formed.

985. (7.) *Limestone*. This rock has generally a white or grey colour, is composed of shining granular concretions, and is more or less translucent. It frequently contains scales of mica and grains of quartz, seldom or never grains and crystals of felspar.

SUBJECT. 2. *Plutonian or Ignigenous Primitive Rocks.*

986. (1.) *Granite*. The structure and composition of this granite is in general the same as that of the Neptunian kind already noticed. It differs from it in occurring in vast and often widely extended masses, which form the central parts of mountain groups, and appear to have come from below after the deposition of the Neptunian rocks that rest upon them. The highly inclined position of the primitive strata is considered to have been occasioned by this granite, with its syenites and porphyries.

987. (2.) *Syenite* is a compound of felspar, hornblende, and quartz; in short, it is a granite in which the mica is replaced by hornblende. Some of the primitive traps belong to this head.

988. (3.) *Porphyry* is a rock with a felspar basis, including grains and crystals of felspar and quartz, and sometimes scales of mica. This porphyry is a mere modification of granite.

989. (4.) *Protogine* is a granular compound of felspar, quartz, and chlorite. It differs from granite in the mica being replaced by chlorite.

990. (5.) *Serpentine* is a simple green-coloured rock, with a compact fracture, feeble translucency on the edges, which yields readily to the knife, and feels greasy.

991. (6.) *Diallage rock* is a compound of felspar and diallage. It belongs probably to the primitive trap series.

SECT. VII. *Transition Rocks.*

992. *The rocks of this class*, in the regular succession, rest immediately upon those of the

primitive class. They generally in this country (Scotland) occupy a higher level than the secondary, but a lower one than the primitive formations. Most of the rocks are distinctly stratified, and the strata are frequently vertical, and, like those of the primitive class, exhibit the same general direction throughout great tracts of country. Some of the deposits are of a chemical, others of a mechanical, nature; limestone is an example of a chemical, greywacke of a mechanical, deposit. They are negatively distinguished from primitive rocks by the absence of fossil organic remains, and the positive characters are drawn from the occurrence of certain fossil crustaceous animals, shells, and corals. The extensive deposits of limestone, particularly of the variegated kinds so highly prized for ornamental purposes, which they contain; the fine granites and porphyries which they afford; and the ores of lead and copper distributed among them, are proofs of their importance in the arts. In this class there are also Neptunian and Plutonian rocks. The *Neptunian* are the following, viz. 1. Greywacke. 2. Transition clay slate. 3. Gneiss and mica slate. 4. Quartz rock. 5. Red sandstone. 6. Limestone. 7. Glance coal. The *Plutonian* are, 1. Granite. 2. Syenite. 3. Porphyry. 4. Trap. 5. Serpentine.

SUBJECT. 1. *Neptunian Transition Rocks.*

993. (1.) *Greywacke* is a conglomerated rock, having a basis of clay slate, in which fragments of various primitive rocks, as clay slate, quartz rock, &c. occur imbedded. When the imbedded fragments become very small, and the quantity of the basis increases, the rock acquires a slaty fracture, and is named *greywacke slate*.

994. (2.) *Transition clay slate*. This is the rock known under the name *roofing slate*. It sometimes contains trilobites.

995. (3.) *Gneiss and mica slate*. These have the same general aspect as the varieties met with in primitive regions.

996. (4.) *Quartz rock*. This rock very much resembles the kinds met with in primitive mountains.

997. (5.) *Limestone*. It frequently occurs with less lustre and translucency than primitive limestones, and often exhibits in the same bed various tints and shades of beautiful colours. It is frequently traversed by veins of calcareous spar. Some varieties are conglomerated, forming the *brecciated marble* of artists; and others contain fossil shells and corals, and also the characteristic *trilobite*.

998. (6.) *Glance coal, or Anthracite*. Beds of this coal, known by its metallic lustre, and burning without flame or smoke, are met with in transition districts.

SUBJECT. 2. *Plutonian Transition Rocks.*

999. (1.) *Granite*. This rock does not differ materially from that of the primitive period. It is principally distinguished by its being intermingled with greywacke and other transition rocks.

1000. (2.) *Syenite*. This rock, which has the same mineralogical characters with the primitive varieties, very generally contains crystals of sphene.

1001. (3.) *Porphyry*. This porphyry has sometimes a basis of felspar, sometimes of clay stone, and as usual contains imbedded grains and crystals of felspar. It occurs either alone, or associated with syenite and trap, forming mountains, and even ranges of mountains.

1002. (4.) *Trap*. In this as in the primitive trap, the sole and always the predominating mineral is hornblende. It passes into syenite.

1003. (5.) *Serpentine*. This rock does not differ materially from the primitive rock of the same name: geognostically it is distinguished from it by its alternating with, and sometimes traversing in the form of veins, greywacke and other characteristic transition rocks.

SECT. VIII. *Secondary Rocks.*

1004. This very interesting class of rocks rests, in the regular succession, immediately upon those of the transition class. In this country they generally occupy a lower level than the transition formations, and the districts where they prevail have also a different external aspect or physiognomy. Much of the mineral matter of which they are composed appears to have been deposited from a state of mechanical suspension, a circumstance which may be considered as distinguishing them, in some measure, from the transition class, where chemical deposits prevail over those of a mechanical nature. They abound in fossil organic remains, and it is here that for the first time we meet with remains of vertebrated animals, as *lacertæ* and other species of the same general description. *Coal*, which occurs but in small quantity in transition deposits, is profusely distributed among secondary formations. Of ores, by far the most abundant, and at the same time the most important in an economical view, are those of *iron* and *lead*: of these the iron (it is the common clay ironstone, the aluminous carbonate of iron,) is the most abundant and most widely distributed. In this, as in the preceding class, there are Neptunian and Plutonian rocks. The Neptunian rocks

are the following: — 1. Sandstone. 2. Slate. 3. Limestone. 4. Gypsum. 5. Coal. The Plutonian are, 1. Granite. 2. Porphyry. 3. Trap.

SUBJECT. 1. *Neptunian Secondary Rocks.*

1005. *In the primitive and transition classes* geologists have not hitherto observed any very determinate arrangement among the Neptunian deposits; whereas in the present class a determinate order has been discovered throughout the whole series. In our sketch we shall follow the order of succession, beginning with the oldest, and finishing our account with a description of the newest formation. The whole Neptunian series is divided into formations of sandstone and formations of limestone; the other members of the series, as the slate, gypsum, coal, and ironstone, occurring subordinate to these.

1006. *First secondary formation; or the old red sandstone.* This formation is a sandstone of a red colour, and, being the oldest of the sandstones, is named the *old red sandstone*. It is composed of particles of quartz, with occasional scales of mica and fragments of felspar, held together by an iron shot basis or ground. Sometimes it is associated with a *conglomerate* made up of fragments of transition and primitive rocks.

1007. *Second secondary formation, or mountain limestone, or metalliferous limestone, or carboniferous limestone* of geologists. This deposit rests, generally conformably, sometimes also unconformably, on the old red sandstone. It is distinctly stratified, and the strata are frequently more or less inclined. Its colours are generally grey; the fracture is compact. Sometimes it has a granular foliated structure, particularly where it occurs in contact with trap rocks. Some varieties, viz. those named *lucullite*, have a black colour. It contains fossil organic remains of animals of various descriptions. Of these the most characteristic are genera of the *trilobite* tribe. It is much to be wished that those naturalists who have the opportunity would institute a rigid comparison of the mountain limestone, or the limestone immediately below the great coal formation, and the transition limestone which alternates with greywacke.

1008. *Third secondary formation; or the second secondary sandstone, or the great coal formation.* This very important deposit is a compound formation, therefore consists of different rocks. Of these rocks the predominating one is sandstone. The rocks of the formation are the following: — 1. Sandstone. 2. Slate. 3. Clay. 4. Limestone. 5. Coal. 6. Ironstone. 1. *Sandstone.* The general colours are white and grey; sometimes also it is reddish, and then it much resembles the old red sandstone. Some varieties are entirely composed of particles of quartz, held together by a very inconsiderable basis or ground; others contain besides quartz also felspar and mica; these are by some geologists named *arkose*. It frequently contains coaly matter, and casts and impressions of plants. — 2. *Slate.* Of the slate there are two kinds, named slate clay and bituminous shale, both of which are mere modifications of clay with the slaty structure. These also contain fossil organic remains. — 3. *Clay.* This is compact clay without the slaty structure, and from its use in the arts is named fire clay. — 4. *Limestone.* This limestone very much resembles the mountain limestone which lies below the coal; but hitherto no trilobites have been found in it. It alternates in beds with the other rocks of this formation. Some geologists refer it to the mountain limestone, and consequently that limestone to the coal formation; an opinion which may be correct. — 5. *Coal.* The coal in this formation occurs in beds that alternate with the slates, sandstone, and limestones. The coal is bituminous or black coal. — 6. *Ironstone.* This ironstone is the common grey clay ironstone of mineralogists. It is an aluminous carbonate of iron, and is the species of ironstone which affords most of the iron manufactured in this island. It occurs in beds or imbedded, and most frequently in the slate of this formation.

1009. *Fourth secondary formation; the second secondary limestone; the magnesian and alpine limestone* of authors. This formation, in the regular succession, rests immediately upon the coal formation. It contains several varieties of limestone. One of these, which frequently occupies the lowest part of the deposit, has a brownish black colour, a thick slaty fracture, and emits an animal bituminous smell, and is named *bituminous marl slate*. Another variety has a yellowish grey, or even at times an ochre yellow colour, with a compact or small granular foliated structure, with a low degree of lustre, and is named *magnesian limestone*. Another variety has a brownish or yellowish colour, is sometimes compact, sometimes granular or cavernous, impregnated with sparry iron, forms the upper part of the deposit, and is called *calcaire ferrifère*. When this variety becomes charged with bitumen and cavernous, it is named by German miners *rauchwacke*. It abounds in the fossil shell named *Productus aculeatus*. This formation does not abound in fossil organic remains. No true ferns, but fossil *fuci* and *zosteræ*, occur in it. Remains of the *monitor*, and it is said also of the *crocodile*, have been met with in it. Fishes of the genus *chætodon* and of other tribes, and numerous remains of shells and corals, occur more or less frequently in different varieties of the limestone. The *trilobite* tribe, so abundant in the transition period, and also in the first secondary limestone, occur here along with *orthoceratites*. It is the species named *trilobites bituminosus*. *Entrochi* and *pentacrini* of great

size also occur in it. The shells are not distributed throughout the whole mass of the beds, but rather occur in particular parts. The following are the shells: —

Orthoceratites, very rare.

Ammonites gibbosus.

Terebratula paradoxa.

Terebratula elongata.

Spirifer alatus.

Encrinus racemosus.

Productus rugosus.

Mytilus rostratus.

Terebratula ovata, lacunosa, trigonella.

1010. *Fifth secondary formation*; the *third secondary sandstone*, or *variegated sandstone*, or *new red sandstone*. In this formation, besides the sandstone, there are, when the deposit is complete, also beds of marl, with gypsum and rock salt. The *inferior part* of this formation is a red coloured sandstone conglomerate, which rarely contains subordinate beds of dolomite, but no fossil organic remains. Above this reposes what may be called the *middle part* of the deposit, which is the variegated sandstone, so named because it sometimes exhibits different colours, principally red, with yellow and grey blotches. It is composed of fine grains of quartz, with a little mica, and sometimes felspar, held together by a base of ferruginous clay. It contains but few organic remains, principally of vegetables. The *upper part* of the deposit is generally composed of beds of a clayey marl, always more or less slaty, and generally alternating in the lower part with beds of the sandstone. Its colours are red, grey, and yellow; sometimes it is variegated in the same manner as the sandstone with which it alternates. It contains subordinate beds of *gypsum* and *rock salt*, and sometimes also beds of *dolomite*. It contains littoral shells and bones of *saurian* animals.

1011. *Sixth secondary formation*; the *shell limestone*, or *muschel kalkstein*. This interesting deposit, (the only formation of the secondary class wanting in Britain,) in the regular succession, rests immediately upon the variegated or new red sandstone formation. This limestone is of a grey, yellow, or reddish tint of colour. — It is compact, but the fracture surfaces exhibit numerous shining facets from animal fossil remains. Beds of marl, which are sometimes oolitic, alternate with it. It often abounds in well-preserved fossil shells; hence the name shell limestone. It some times contains *gypsum* and *rock salt*. It contains besides numerous species of fossil shells, often very well preserved, bones of great saurian animals, and impressions of fuci and ferns. Corals and echinites are rare, but entrochites are sometimes so abundant that in some parts of Germany it is named trochital limestone (trochiten kalk). The *Encrinites liliiformis*, very common in this formation, is considered to be characteristic of it. Of the fossil shells, the *Ammonites nodosus* and *Avicula socialis* are considered as characteristic of the shell limestone.

1012. *Seventh secondary formation*; the *third secondary sandstone*, *red ground*, *marnes irisées*, *Keuper*. This deposit is principally composed of sandstone, marls, and dolomites with salt and gypsum. It has been divided into the following four groups: — 1. Keuper salt and gypsum. 2. Inferior keuper. 3. Variegated marls. 4. Upper or superior keuper. — The *salt* and *gypsum*, with their marls and beds of saline clay, the most important members of this formation in an economical point of view, occupy the lowest part of the series. Several extensive salt-mines occupy this situation. — The *inferior keuper*, that which rests on the gypsum and salt, is a sandstone which is red in the upper strata, but gradually passes into grey in the lower. This sandstone sometimes alternates with marls, slate clay, and dolomites, and contains beds of gypsum and coal. The slate clay contains bivalve shells, a species of *Ophiura*, and several species of *Equisetum*, *Filices*, and also some *Cycadaceæ*. — The *variegated marls* (*marnes irisées*), resting upon the inferior keuper, exhibit alternate stripes of white, green, violet, red, grey, and blue; they are generally compact or slaty, and soft. They contain few or no organic remains, very little gypsum, and no rock salt. — The *upper keuper* is sandstone of a grey, yellow, or variegated colour. It is composed principally of grains of quartz, generally but loosely held together, so that the mass can frequently be pressed into grains between the fingers. Contains some traces of coal, and a few fossil shells and impressions of plants.

1013. *Eighth secondary formation*, or *fourth secondary limestone*, contains the *lias* and *oolite limestones* and *Jura limestone* of authors. This, which is one of the most extensive and important of the secondary formations, may be divided into the following members; proceeding, as usual, from below upwards: — 1. Lias. 2. Oolite. 3. Oxford clay. 4. Coral rag. 5. Kimmeridge clay. 6. Portland oolite.

(1). *Lias*. Lias is a provincial name applied to limestone shales, and marl stones, and some sandstones that occur along with them. The marls are sometimes very bituminous, and contain beds of lignite or brown coal, and also fossil shells, and occasionally beds of gypsum. The fossil vegetables of the lias are lignites, fossil wood, sometimes siliceous impressions of ferns, *cycadaceæ*, and fuci. The animal remains are numerous and interesting. It is in this deposit that bones and skeletons of extinct tribes of saurian animals are met with; such as the genera *geosaurus*, *ichthyosaurus*, and *plesiosaurus*. Different species of *fishes* and of *crabs* also occur. The lias contains an immense quantity of fossil shells, of

which the predominating one is the *Gryphæa arcuata*; hence the marl stones or limestones of the lias have been named gryphite limestones. Besides, the following may also be mentioned as characteristic fossils, viz. *Ammonites Bucklandii*, *Plagiostoma gigantea*, *Belemnites paxillosus*, and *Belemnites digitalis*.

(2.) *Oolite*. The oolite is divided into inferior oolite and great oolite. *Inferior oolite*. This is a limestone composed of round granular concretions, resembling the roe of fishes; hence the name oolite, or roestone, given to it. It is associated with compact limestones and marls, and sometimes it abounds in fossil organic remains. It contains, as at Brora in Sutherland, beds of coal. The fossil vegetables, which are numerous and often well preserved, are of the fern and cycas tribes. It also contains bones and skeletons of great extent, saurian animals, also tortoises and crabs. Species of the tribe echinus, which makes its first appearance in the eighth secondary formation, are not uncommon; the crinoid family has also representatives here, so also have several genera of the coral tribe. The characteristic fossil shells of the inferior oolite are the *Belemnites aalensis* and *Bel. sulcatus*. — *Great oolite*. This is a thick deposit, composed chiefly of an oolitic limestone. It contains beds of dolomite, and sometimes rests upon beds of *fullers' earth*. Resting upon this oolite is the *Bradford clay*; next the *forest marble*, to which belongs the *lithographic limestones* of Bavaria. This forest marble, which includes also the *Stonesfield slate*, contains remains of *flying reptiles*, *terrestrial mammifera*? *saurian animals*, *insects*, *marine shells*, and *vegetables*. The upper member of this great oolite series is named *cornbrash*, which is a bluish and whitish compact limestone with marl.

(3.) *Oxford clay* and *Kelloway rock*. The Oxford clay is a bluish argillaceous marl, which becomes brown on exposure to the air. It contains subordinate beds of calcareous marl, and also the calcareous clayey nodules, named *septaria*. Underneath is the Kelloway rock, a particular kind of calcareous rock. The marls sometimes contain bones of the ichthyosaurus. The fossil shells are pretty numerous, but our limited space will not allow an enumeration of them.

(4.) *Coral rag* is a loosely aggregated calcareous rock, abounding in different species of madrepores; the rock is sometimes marly, and of a grey colour. Below the coral rag is a bed of ferruginous siliceous sand, containing a calcareous grit or sandstone, and siliceo-calcareous concretions. It is in this part that the fossil organic remains are most abundant and most perfectly preserved. Fossil *Cycadaceæ* occur; also, as in the *calcareous grit*, bones of saurian animals. Nearly all the *madrepores* belong to the genera *Astrea*, *Caryophyllea*, and *Meandrina*. *Echinites* of the genera *Cidaris* and *Clypeus* are met with. The fossil shells have not been thoroughly examined.

(5.) *Kimmeridge clay*. The lower beds of the preceding deposit alternate with a blue or yellowish grey marl, which is more or less slaty, and contains beds of a very bituminous slate, and even true lignite or brown coal, sometimes forming beds of considerable thickness. An ichthyosaurus different from that in the lias is found here; also remains of the plesiosaurus, and bones of whales, it is said, have been found in the Kimmeridge clay; also fine impressions of fishes. *Serpula*, also species of *cidaris* and *asterias*, occur in this formation. Many species of different genera of marine shells are enumerated as occurring in it, particularly *ammonites*, *belemnites*, &c. It would appear that the prevailing fossil shells in the whole oolite formation are *ammonites* and *belemnites*. The belemnites do not occur lower down in the series than the lias.

(6.) *Portland oolite*. This is a limestone which is frequently loosely aggregated, sometimes oolitic, forming the last deposit of secondary limestone with this structure, none of the superior or newer secondary limestones possessing it. It contains petrified monocotyledonous and dicotyledonous plants. Remains of large saurian animals, and also of fishes, are met with in it. *Ammonites*, *trigonia*, and *gryphites*, are abundant. The most characteristic shells are the *Ammonites triplicatus* and the *Pecten lamellosus*. A *cidaris* and *madrepore* have also been discovered in it.

1014. *Ninth secondary formation*. *Wealden clay* and *Purbeck stone*. This remarkable formation abounds in fresh water shells and land plants; but, in England at least, contains no marine species; hence it is an example of a fresh water deposit between two marine deposits, viz. the oolite and chalk. It is probable, however, that future observations will prove that even in England it contains marine shells. There are two members of this formation, viz. the Weald clay, and Purbeck stone.

(1.) *Weald clay*. This is a bluish or greyish coloured clay, containing subordinate beds of argillaceous limestone. The limestone abounds in shells belonging to the fresh-water genus *paludinæ*; also a great quantity of the crustaceous tribe named *cypriis*. *Brown iron ore*, beds of *lignite*, and beds of sandstone much resembling some of the varieties of the coal formation, also occur in it. It contains impressions of ferns, but of different species from those in the coal formation.

(2.) *Purbeck stone* is a clayey limestone, which alternates with marls. It abounds in *paludinæ*, also contains beautiful impressions of fresh-water fishes, and of tortoises and crocodiles.

1015. *Tenth secondary formation, or chalk formation.* This formation is well characterised. by its organic remains and flints. Five beds occur in this formation; viz. 1. *Lower green sand.* 2. *Gault clay;* 3. *Upper green sand;* 4. *Tuffaceous chalk;* 5. *Chalk.*

(1.) *Lower green sand.* This sand does not differ from the upper; but the fossil organic remains are less abundant. The shells are ammonites, terebratulites, trigonia, &c. In this island the *trigonia alæformis* is considered as characteristic of this lower green sand.

(2.) *Gault.* The green sand is divided into two by a very thick bed of bluish grey clay, known in many of the districts where it occurs under the name of gault. It contains ammonites and other shells, particularly the *Inoceramus sulcatus*.

(3.) *Upper green sand.* The lower part of the tuffaceous chalk, containing a prodigious quantity of fossils and of iron pyrites, becomes more and more charged with green points, and we reach a mass composed of a green sand more or less marly, and often a green coloured calcareous sandstone. Fragments of silicified wood, and also parts of shells penetrated with silica; teeth of fishes, but parts of no other vertebrated animals, occur in it. The fossil shells are very numerous: species of the genera *cidaris* and *spatangus* are met with, and also corals of various kinds.

(4.) *Tuffaceous chalk,* which is generally composed of a cretaceous matter, clay and sand. It is softer than chalk, and towards the lower part of the mass the clay predominates, and slaty clay marl is found. When the sand predominates, a loosely aggregate greyish sandstone is formed. No flints occur in this tuffaceous chalk, their place being taken by chert. Fossil vegetables, even lignite, are found in it. Fossils are most abundant in the lower part of this deposit. The chief are *belemnites*, *ammonites*, *nautilites*, *hamites*, *baculites*, *turritiles*, *echinites*, with *madrepores* and *encrinites*.

(5.) *The uppermost* is the *chalk* properly so called, of which there are two principal kinds, viz. the *upper* or soft or common chalk, which abounds in flints in beds, veins, and imbedded masses; and the *lower* or hard chalk, in which flint is more rarely met with. These chalks also contain iron pyrites and calcareous spar. The fossils are *vertebræ* and *teeth of fishes*; numerous *echinites* and *terebratulites* occur throughout the whole mass; and in the descending order, *ammonites* and *belemnites* first make their appearance in the lower part of the chalk.

SUBJECT. 2. *Plutonian or Igneous Secondary Rocks.*

1016. *Igneous rocks* appear, at different determinate periods, to have broken in among the Neptunian rocks of this class, and also to have forced up through them older rocks of various descriptions, forming mountains, mountain ranges, and groups of mountains. The igneous rocks are porphyry, trap, and sometimes also granite and syenite.

SECT. IV. *Tertiary Rocks.*

SUBJECT. 1. *Neptunian Tertiary Rocks.*

1017. *The rocks of this class were first pointed out by Werner*; but it was not until the publication of the excellent work of Cuvier and Brongniart on the geology of Paris that their importance was felt and acknowledged by geologists. In the regular succession they rest immediately upon the chalk or uppermost member of the secondary class. Although the rocks are looser in texture than those of the secondary class, yet among them beds occur equally compact with those of the secondary class. They abound in fossil remains of the animal and vegetable kingdoms; although many species are different from the present ones, many of the genera are the same. The following are the Neptunian rocks in the order of their occurrence, from below upwards: — 1. *Plastic clay.* 2. *Calcaire grossier, or London clay.* 3. *Gypsum with bones.* 4. *Superior marine sandstones and sands, sandstone of Fontainebleau.* 5. *Upper fresh-water formation.*

1018. (1.) *Plastic clay.* This clay is frequently divided into two beds by a bed of sand; the upper bed is more or less mixed with the sand, the lower bed is pure, kneads completely with water, and is infusible in the porcelain furnace. The upper bed abounds in fossil remains; the lower bed contains none. *Jet* and *brown coal*, which are fossilised remains of dicotyledonous and monocotyledonous plants, occur in it. Remains of the *palm tribe* are very frequent; but ferns have not been met with. *Insects* well preserved in *amber* are also met with. The fossil shells are partly fresh-water, partly marine, which are sometimes separate, sometimes mixed together.

1019. (2.) *Calcaire grossier, or à cerites* of French authors, the *London clay* of English geologists. This deposit is sometimes separated from the plastic clay by a bed of sand, which occasionally contains pure and solid sandstone, but no petrifications. Resting upon this sand is a bed of shelly limestone, abounding in green coloured grains of silicate of iron, and which sometimes passes into a kind of sand; it is in this limestone that the *nummulite* shells are so abundant, and which are mixed with corals and numerous shells in a high state of preservation. Immediately above this lies the great bed of true *calcaire grossier*. It is so compact, that in the Paris basin, where it abounds, it is used extensively as a building stone. It is the common building stone in Paris. It contains marine shells

well preserved, and also remains of plants. In some districts it is divided into two beds by an interposed bed of *lignite* or *brown coal*, which is intermixed with fresh-water shells. It is interesting to notice, that here a limestone abounding in marine shells is separated into two beds by an interposed mass of coal, filled with fresh-water shells. Around London there is a great deposit of clay abounding in the same shells as occur in the *calcaire grossier*; hence, for this and other reasons, it is considered as the equivalent of the Paris *calcaire grossier*. The uppermost part of this formation consists of sand, hornstone, and sandstone, with alternating beds of limestone. It sometimes abounds in *cerites*.

1020. (3.) *Gypsum with bones*. This deposit may be considered as consisting of three stages; a lower, a middle, and an upper. The *lower part*, or that which rests immediately upon the *calcaire grossier*, consists of grey and white limestone, more or less compact, penetrated in all directions by silica. This silica, when it finds its way into cavities in the limestone, lines them with chalcedony or with quartz crystals. It contains species of the fresh-water genera *Lymnea* and *Planorbis*. The *middle part* is composed of gypsum, which alternates with layers of marl. It is in this gypsum that remains of the genera *Palæotherium*, *Anaplotherium*, of various carnivora, also different species of birds and of fresh-water fishes, likewise the *Tronex*, *Testudo*, and *Crocodylus*, are met with: and of the shells, the most characteristic is the *Cyclostoma mumia*. Here also in the marls occurs that curious kind of opal named *menilite*; a mineral which in some degree may be considered as characterising this gypsum deposit. In this gypsum is situated the salt of Wielickza. The *upper part* consists of marls, with fresh-water shells of the *lymnea* and *planorbis* tribes, remains of fishes, and frequently remains of the palm tribe.

1021. (4.) *Superior marine sands and sandstones*. The *lower part* of this deposit is a green-coloured argillaceous marl with *celestine*, upon which there are marls containing fossil oysters. The *middle part* consists of micaceous sands, and sandstones without shells. The *upper part* is sandstone with marine shells.

1022. (5.) *Upper fresh-water formation*. The *lower part* of this deposit consists of sands, marls, and vesicular quartz or millstone (*meulière*), without shells. The millstone occurs rarely in beds, usually in angular masses in the marls and sands. The *upper part* consists of calcareous marls, limestones, and millstones, containing fresh-water shells. This formation contains of fossil plants, species of *Exagenites*, *Lycopodites*, *Poacites*, *Chara*, and *Nymphaea*. It is further characterised by the numerous fossil fresh-water shells of the same genera as occur at present in the neighbourhood, but of different species. The genera are, *Lymnæa*, *Planorbis*, *Potamides*, *Cyclostoma*, *Helix*, and *Bulimus*. This *gyrogonites* of Lamarck, which are small round grooved bodies, are not animal remains, but seeds of the plant *chara*.

1023. *M. Desnoyers describes a marine deposit met with in the basin of the Loire*, as resting upon the upper fresh-water formation. The deposit appears to be the same as the *crag* of English geologists, and has been lately met with also in Provence.

SUBSECT. 2. *Plutonian or Ignigenous Tertiary Rocks.*

1024. *The rough felspathose porphyries*, known under the name *trachyte*, which occur in vast abundance in many countries, appear to be of the same age with the tertiary rocks. *Basalt*, a greyish-black compound of augite and felspar, in which the minerals are not distinguishable by the naked eye; *greenstone* or *dolerite*, a compound, but of a green colour, in which the augite and felspar grains are distinguishable; *wacke*, which is a clayey greenstone; *amygdaloid*, which is greenstone or wacke with the amygdaloidal structure; and *clinkstone* or *phonolite*, which is a slaty felspar, are found associated with tertiary rocks. Some classes of mountains, as Mont Blanc, and the Scandinavian ranges, are conjectured to have been upraised partly during and partly after the deposition of the tertiary rocks.

SECT. X. *Alluvial Rocks.*

1025. Under this head we include the various *calcareous deposits*, peat, clays, loams, sands, gravels, and rolled masses or boulders, which, in the regular succession, rest upon the newest or uppermost rocks of the tertiary class. These deposits have been variously arranged according to their supposed relative antiquity: probably they may be arranged with sufficient distinctness, according to their situation, in the following manner: — 1. *Littoral* or sea-coast *alluvium*, as downs. 2. *River alluvium*, that met with on the bottom and sides of rivers. 3. *Lake alluvium*, that on the sides, &c. of lakes. 4. *Spring alluvium*, that formed by springs, as *calc tuffa*, *calc sinter*, *travertine*, *siliceous sinter*, &c. 5. *Rain alluvium*, that deposited by and moved by rain water. 6. *Plutonian alluvium*, that formed and distributed over tracts of country by the upraising of chains of mountains.

1026. *In this alluvium*, remains of vegetables and animals are of frequent occurrence. The vegetables, as far as is known at present, are either foreign species or species identical with those of the country where their remains are found. In the older or Plutonian alluvia, neither remains of human industry nor bones of the human species have been found; but numerous bones and skeletons of land quadrupeds.

1027. *These quadrupeds are either of extinct species of living genera, as the elephant, rhinoceros, hippopotamus, tapir, bear, and lion; or of living species, as the beaver, rat, ox, deer, sheep, and dog; or species of extinct genera, as mastodon and megatherium.*

SECT. VI. *Volcanic Rocks.*

1028. *These are rocky masses which owe their origin to volcanoes. They are divided into old and new, or ancient and modern, or extinct and active.*

1029. *Ancient volcanic rocks.* Under this division we include those volcanic rocks connected with volcanoes, which have not been in a state of activity since the commencement of our history. These rocks very much resemble basalt, and have been sent from the interior of the earth in the form of streams or currents. In almost every country where they occur, we find *craters* from whence they have streamed. These dark-coloured basaltic-like rocks, are accompanied with puzzolana and scorïæ, very much resembling those of active volcanoes. Sometimes lighter coloured lavas, named *leucostine*, and which resemble trachyte, occur along with the darker varieties.

1030. *Modern volcanic rocks.* These, as already enumerated and described at p. 204, 205., are lavas, scorïæ, ashes, sands, &c.

BOOK III.

GENERAL PRINCIPLES OF GEOGRAPHY UNDER ITS RELATION TO ORGANISED AND LIVING BEINGS.

1031. *In considering the extensive range of subjects which this book embraces, we have arranged them as they successively rise above the scale of inanimate nature.*

1032. *The first chapter treats of geography, in its relation to botany, or to the distribution of plants over the surface of the globe.*

1033. *The second chapter considers it in its relation to zoology, or the distribution of animals, including man viewed simply as to his physical condition.*

1034. *The third chapter views geography in reference to human society, to man in his political, moral, and social condition.*

CHAP. I.

GEOGRAPHY CONSIDERED IN RELATION TO THE DISTRIBUTION OF PLANTS.

1035. *In proportion as our knowledge increases relative to any of the sciences, we find a more intimate relation and connection between them. Formerly geography was only studied as it regarded the surface of the earth itself, its figure, the constitution of the several regions and countries, their boundaries, &c.; and botany has had too many votaries who devoted their attention almost exclusively to determining the generic and specific names of plants, neglecting the more beautiful and philosophical parts of the science. Of late years, indeed, our systems of geography have, in some instances, contained a meagre catalogue of the vegetable productions of the different regions, but nothing that could give the least information with respect to the laws of their general distribution: and now that some of the most able naturalists and philosophers of our day have, by their labours, thrown new light upon this interesting subject, we should feel that our work would ill merit the character which we hope it may obtain with the public, were we to omit a notice of it. At the same time, the limits of our publication will permit us to give only a sketch of what indeed must be considered as still in its infancy; and those who have most devoted their attention to botanical geography will most readily join with Mirbel in declaring that "we are even yet far from having arrived at that period when it will be possible to write a good history of this subject. What we do know of climates and of vegetation, is little, in comparison with what we have yet to learn; and hence it would be rash in us to form an estimate of what we do not know by what we are already acquainted with. The surest way is to confine ourselves to collecting and arranging facts, leaving, to those who may follow us, the charge of discovering and developing the theory."*

1036. *To exhibit the present state of botanical science, we shall endeavour to put together the more interesting facts, collected principally from the writings of our most authentic travellers and naturalists; and, devoting this memoir to vegetable geography in its more enlarged and general sense, shall afterwards, in the different countries, under the head of botany, point out*

some of the most striking and important productions of their respective regions. As the nature of the present work does not permit us to enter minutely into the subject in all its bearings, we shall give a popular view of it, as little encumbered as possible with technical terms.

1037. *That certain vegetables are confined to certain districts or limits*, depending in a great measure, but by no means altogether, upon soil and climate, must be familiar to the most careless enquirer into the works of nature. In regard to climate, the two extremes are represented by the country within the tropics, and that which approaches the poles. In the one, nature exhibits herself in her most lovely and her most magnificent and exuberant form, and the earth is covered with vegetables which indicate a never-ending summer; whilst in the others a brief summer, a few days of freedom from frost and snow, call into existence a thinly scattered vegetation of small and stunted flowering plants, which scarcely rise above the mosses and lichens that surround them; and the intermediate zones will be found to be occupied by other races, gradually, however, increasing in difference as they approach to one or other of these extremities. The same gradation exists, we know, upon a lofty mountain situated within the tropics. At its base may be seen those plants which are peculiar to the tropics; and the beauty, the grandeur and perpetual verdure will gradually diminish in the ascent, until a soil and climate be found on the higher summits similar in respect to climate and productions to those in the vicinity of the poles.

1038. *In regard to climate and vegetable productions*, our globe has been aptly compared, in its two hemispheres, to two immense mountains, placed base to base, the circumference of which at the foot is constituted by the equator, and the two poles represent the summits, crowned with perpetual glaciers.

1039. *That almost every country possesses a vegetation peculiar to itself*, is also well known; and this is particularly the case with countries whose natural boundaries are formed by mountains, seas, or deserts, even in the same or different degrees of latitude. Europe exhibits a widely different class of plants from that part of North America which lies immediately opposite to it. The botany of Southern Africa has little or no resemblance to that of the same parallels in South America, or to that of New Holland. Nay, in our own country of Britain, we have some plants that are confined to the eastern and some to the western side of the kingdom. In Scotland, the *Tutsane* and the *Isle of Man Cabbage* are never found but on the western side of the country, and the same is the case with the *pale Butterwort* (*Pinguicula Lusitanica*), both in England and Scotland. Nature has constituted the barrier, for by art they may be cultivated as well on one as the other side of the island.

1040. *Botanical geography is constituted* by considering plants in relation to their *habitation*, region, or the country in which they grow, and in regard to their locality or particular *station*, and forming a collection of facts, deduced from these circumstances, from which general laws may be derived: nor is this a science destitute of advantages; such, we mean, as are immediately manifest; for there are few, in the present age, who will be disposed to deny that the study of the works of nature, like every thing that can exalt and refine the mind, is highly deserving of our attention. Vegetable geography is intimately connected with horticulture. Our gardens will be better stocked with vegetables and fruits, our forests with trees, our fields with corn, and our pastures with grasses, in proportion to our knowledge of the relation of plants with the exterior elements. Nay, Schouw has justly observed, that a good chart of the distribution of the vegetable forms over any given country will afford a far more correct idea of the productive strength of that country than many statistical tables. The systematic botanist may thence derive benefit; for by it he will be better able to determine whether certain kinds of plants are species or varieties; he will consider that a different local situation produces different effects upon them; that those growing in wet places are less hairy or downy than those growing in dry; that at great elevations plants are more dwarf in their stature, with fewer leaves, but with larger and more brilliant flowers than those found at lesser heights. The station, too, of certain plants, or groupes of plants, frequently leads to a discovery of characters diverse from other individuals of other countries with which they had been associated. Thus the *Canadian Strawberry* and the *Canadian chickweed Wintergreen* (*Trientalis*), though long confounded with our *Strawberry* and with our *Trientalis*, are found to be quite distinct. The regions, too, and the limits of those regions, of very important medicinal drugs, are determined by vegetable geography.

SECT. I. *Progress of Botanical Geography.*

1041. *This branch of science had been, however, for a long time, wholly neglected.* Linnæus, indeed, with whom originated so many improvements in botany, besides what related to systematic arrangement, was the first writer who gave stations for plants, as he called them, or rather habitations, or frequently both combined, and this plan has been followed by every succeeding systematic botanist. Yet although these stations or habitations are frequently consulted in the geographical arrangement of plants, they are too vague and uncertain to

be generally depended upon ; and they must be employed with caution. We are not, however, to forget, with regard to Linnæus, that he has, in some of his writings, entered far more fully into the subject than any of his predecessors. In his beautiful memoir entitled *Stationes Plantarum*, he divides all, primarily, into *Aquatic*, *Alpine*, those growing in *shady places* (*Umbrosæ*), those growing in *open ground* (*Campestres*), *Mountain-plants*, and *Parasitical* ; and these again are subdivided into *fresh-water*, *maritime*, *marsh-plants*, *heath-plants*, &c. ; and in his oration entitled "*De telluris habitabilis incremento*," he has published that ingenious if not correct theory of the origin and distribution of all plants as well as animals ; namely, that, at the beginning, the whole earth was covered with sea, except one island, large enough to contain all the animals and vegetables ; that this island was situated within the tropics, and was crowned with a very high mountain, which, in consequence of its varied soil and climate, might contain one or more of every vegetable and animal. He then proceeds to show how, by means of the amazing fertility of plants from seed, they might, at an after period, be scattered all over the globe in the soil and situation best adapted to them ; and, lastly, in his *Flora Lapponica*, he pays particular attention to the differences of plants as influenced by the variety of stations, and especially by their altitude above the level of the sea. Tournefort, indeed, is said previously to have found upon Mount Ararat, at its base, the plants of Armenia ; a little way up, those of Italy ; higher again, those which grow about Paris ; afterwards, the Swedish plants ; and lastly, on the top, the Lapland alpine ones. De Saussure, who so assiduously studied vegetable physiology, was particularly attentive, on that account, to the elevation at which plants grow above the level of the sea ; and appears to have been the first to ascertain *that* elevation barometrically. St. Pierre did not leave this subject unnoticed in his *Studies of Nature* ; but he was so led away by his genius, that he believed there was not a square league upon the surface of the globe which did not include within its area some one vegetable, at least, which does not exist any where else. Mr. Young, the celebrated agriculturist, in his *Travels upon the Continent*, determined with considerable accuracy the northern boundaries of several of the most important cultivated plants, the *Olive*, the *Vine*, and the *Maize* ; whilst Girard Soulavie, in the south of France, has characterised the limits of them, and of the *Orange* and *Chestnut* ; and these two men have, no doubt, excited a spirit of enquiry into the geographical distribution of other vegetable productions. These, and several other authors of less note, prepared the way, during the last century, for the more important labours of the present, when the study has begun to rank as a science. Stromeyer, in 1800, described, to a certain extent, the boundaries of the vegetable kingdom, in a work entitled "*A Specimen of the History of Vegetable Geography*," which appeared at Göttingen. The work of Kielmann, edited at Tubingen, 1804, entitled "*A Dissertation concerning Vegetation in the Alpine Regions*," was followed by that of Treviranus, named "*Biologie*," which seems to be the first wherein attention was paid to the distribution of plants according to their natural families ; the latter author dividing the globe into regions or distinct Floras ; and De Candolle, about the same time, partitioned France into regions in the same way, and wrote on the influence of height upon vegetation. To the celebrated M. de Humboldt, however, we are indebted for the most valuable writings on vegetable geography, and those which have first given it the true character of a science. His "*Essai sur la Géographie des Plantes*," in 1807, and his beautiful "*Tableau de la Nature*," contained his first ideas on the subject ; while his celebrated "*Prolegomena de distributione geographica Plantarum secundum cæli temperiem et altitudinem montium*," forming the introductory chapter to the botanical part of his travels ; his invaluable memoir on isothermal lines and the distribution of heat over the globe, published in the *Mémoires d'Arcueil*, and translated into Brewster's and Jameson's *Philosophical Journal*, vol. iii. p. 1. &c. ; together with his latest work on the subject, "*New Enquiries into the Laws which are observed in the Distribution of Vegetable Forms*," likewise inserted in the *Edin. Phil. Journal*, vol. vi. p. 273 : these may justly be considered as the most important dissertations on a comprehensive scale that have yet appeared. In the mean time, other eminent naturalists, by their well-directed labours, contributed materially to extend the science : Wahlenberg, for example, in his admirable *Flora Lapponica*, and in that of a portion of Switzerland, and of the Carpathian Alps ; whilst Von Buch, in his travels in Norway, detailed many curious facts respecting the distribution of vegetables in that climate, and also in his interesting *Voyage to the Canaries*, made in company with the lamented Professor Christian Smith. Mr. R. Brown, who treats with the most masterly hand whatever is connected with the study of botany, has much increased his already eminent fame by those memoirs in which this subject is entered upon ; and his profound knowledge of the natural orders, his possession of the richest herbarium and the finest library in the world, both of which he has turned to the best possible account, together with the advantages arising from his extensive travels ; these have enabled him to publish memoirs which will be studied with infinite advantage, and which will rank among the most valuable that have ever appeared. We particularly allude to his "*Remarks, Geographical and Systematic, on the Botany of Terra Australis*, 1814," and "*Observations on the Herbarium collected by Professor Christ. Smith, in the Vicinity of the Congo*, 1818." Mr. Boué, a foreigner, but for

a long time a resident in Scotland, published a pamphlet at Edinburgh, entitled "*De Methodo Florum cujusdam regionis conducendi*," and Mr. Winch of Newcastle, an "*Essay on the Geographical Distribution of Plants through the County of Northumberland*." Taking advantage of what others had done, Dr. Schouw compiled, in 1824, an admirable history of the science, of which some portions have been translated into Brewster's and Jameson's Journals; and we regret that, to our knowledge at least, this valuable work exists, in an entire state, in no other language but the Danish and the German. It has the merit of being accompanied by an Atlas of several maps of the world; each exhibiting the geographical extent of certain tribes or families of vegetables, indicated by different colours. This plan of the maps has been successfully followed by Dr. Von Martius, in his History of the natural order *Amaranthaceæ*, in the thirteenth volume of the *Nova Acta Acad. Cæsar.-Leopold.*; so that we see, at one view, upon a plan of the world, the countries in which these plants are found, their boundaries, and the comparative abundance, indicated by the greater or less depth of colour employed. De Candolle, again, in the "*Nouveau Dictionnaire des Sciences Naturelles*," has given an admirable *résumé* of all these writers, and has added much important original information. A somewhat similar plan is adopted by M. Brongniart in the "*Dictionnaire Classique d'Histoire Naturelle*," vol. vii. p. 275. Mr. Allan Cunningham, both in Mr. Barron Field's "*Memoirs of New South Wales*," and in the second volume of "*Captain King's Survey of the Intertropical Coasts of Australia*," has furnished some further and very excellent remarks upon the distribution of vegetables, especially of the less frequented parts of New Holland. The "*Mémoires du Muséum d'Histoire Naturelle*" contain some important papers on this subject, particularly that of Mirbel, "*Sur la Géographie des Conifères*," a tribe of plants valuable for its economical uses; and his "*Recherches sur la Distribution Géographique des Végétaux phanérogames dans l'ancien Monde, depuis l'Equateur jusqu'au Pôle Arctique*:" and, lastly, we shall only name a useful little manual, entitled a "*Lecture on the Geography of Plants*," by Mr. J. Barton.

1042. We might yet have swelled this list to a considerable extent; but enough has been said to show that the subject has merited and received the attention of some of the ablest naturalists; and that it is a science which gives an increased degree of interest both to geography and botany.

SECT. II. *On the Influence of the Elements on Plants.*

1043. In regarding the limits to which certain plants are circumscribed upon the surface of the globe, we shall see that it is with them as with the mighty ocean; they are equally subject to that fiat of the Almighty, "Thus far shalt thou go, and no farther." The Palms, the Tree-Ferns, the parasitical Orchideæ, are ever confined to the tropics; the Cruciferous and Umbelliferous plants almost exclusively to the temperate regions; while the Coniferous plants, and many of the Amentaceous tribes, flourish in those of the north: and since these are all affected by physical agents, we must consider, before proceeding any farther, the influences which the *elements* or *exterior agents* exercise upon plants. These M. de Candolle considers to be *Heat, Light, Moisture, Soil, Atmosphere*.

SUBSECT. 1. *On the Influence of Heat.*

1044. *Heat* is the most obvious and powerful agent in affecting the existence and growth of plants: and of this we have continual experience before our eyes. In winter all vegetation is at a stand, and we can only cultivate those plants which are in a continued state of vegetation, by artificial heat. Plants are nourished either by water alone, or by substances dissolved or suspended in the water. Hence vegetation is arrested when the temperature is below the freezing point; for the water, becoming solid, cannot enter the vegetable tissue. Again, as in the great deserts of many countries, the heat may be so great that the earth is dried up, and cannot part with its nutritive properties. These effects, however, it is but reasonable to suppose, are more remarkable upon the surface of the earth than at a considerable depth: hence it happens that trees which have long tap-roots resist both the extremes of temperature better than those whose roots are nearer to the surface; their fibres penetrate into a soil whose temperature is greater in winter than that of the outer air, so that the fluids imbibe and keep the interior of large trees, as has been ascertained by experiment, at a degree of heat pretty nearly the same as that indicated by a thermometer placed at the roots of such trees. Hence, the greater the thickness of the stem or branch, and the greater the number of layers interposed between the pith (the softest part being the moistest and the most susceptible of cold) and the exterior air, the better are they able to resist the severity of the cold. It is a well known fact that a shrub or tree as it grows older becomes more hardened against frost. De Candolle relates, that at Montpellier the *Pride of India* (*Melia Azedarach*) when young is destroyed by a moderate degree of cold; but that when it attains a more advanced age it will endure, in the garden at Geneva, an intensity of atmosphere four times as severe as that which killed the young plant in the south of France.

1045. Again, in proportion as the exterior layers are deprived of sap or watery fluid, and for-

tified by a deposit of carbon and resinous matter, the more powerfully they withstand the cold. Every gardener and cultivator is acquainted with the fact, that in cold and wet summers, when the sun and heat have been insufficient to produce good bark upon the new shoots of the fruit-trees, they are liable to be affected by a very moderate frost in the ensuing winter. Succulent plants and Monocotyledonous plants, in general, which have no distinct bark, are highly susceptible of cold; whilst the *Birch*, which is fenced around with numerous layers of old and dry bark, and the *Fir*, whose bark abounds with resin, endure an intense degree of it without injury. At Fort Enterprise, in North America, lat. $64^{\circ} 30''$, Dr. Richardson has ascertained that the *Banksian Pine* (*Pinus Banksiana*), the *white*, the *red*, and *black Spruce*, the *small-fruited Larch*, and other Amentaceous trees, bear a degree of cold equal to 44° below zero of Fahrenheit; and in Siberia, lat. $65^{\circ} 28''$, the *common Larch*, the *Siberian Stone Pine*, the *Alder*, *Birch*, and *Juniper*, &c. attain their greatest size, and are not affected by the extremest cold of that severe climate.

1046. *Powerful summer heats* are capable of causing trees and shrubs to endure the most trying effects of cold in the ensuing winter, as we find in innumerable instances; and *vice versâ*. Hence, in Britain, so many vegetables, fruit-trees in particular, for want of a sufficiently powerful sun in summer, are affected by our comparatively moderate frosts in winter; whilst upon continents in the same degrees of latitude the same trees arrive at the highest degree of perfection. Even in the climate of Paris the *Pistacia tree* and the *Oleander* will not bear the winter. Yet the winters there are mild in comparison with those which prevail in the environs of Pekin, where the *Oleander* was found by Lord Macartney to remain abroad the whole year; and at Casbin in Persia, where Chardin assures us that the *Pistacia Nuts*, produced in the open air, are larger than those of Syria. On the other hand, the heat of these two countries in summer is infinitely greater than that at Paris; the summer temperature of Pekin especially nearly equals that of Cairo, and surpasses that of Algiers. For the same reason, too, the *Weeping Willow* becomes a large tree in England; while in Scotland, where the winters are at least as mild, but where the summer affords much less warmth, this beautiful tree can only be cultivated in highly favoured situations, and even there its vegetation is exceedingly languid: its young shoots, not ripened by the summer sun, are destroyed even by a slight frost.

1047. Hence the influence of temperature upon the geography of plants is ably pointed out by M. de Candolle under three points of view: — 1. The mean temperature of the year. 2. The extreme of temperature, whether in regard to cold or heat. 3. The distribution of temperature in the different months of the year.

1048. The mean temperature, that point which it has for a long time been the great object of the physician to ascertain, is in reality what is of the least importance in regard to the geography of plants. In a general view, it may be useful to take it into consideration; but the mean temperature is often determined by circumstances so widely different, that the consequences and the analogies to be deduced from it relative to vegetables would be very erroneous.

1049. By attending to the extreme points of temperature, results more limited, but far more exact, are to be obtained. Thus, every locality which, though at only short intervals, affords a degree of cold or heat of certain intensity, cannot but produce plants which are capable of supporting those extreme degrees. When, however, these widely different temperatures recur at very long intervals, man may cultivate in such a country a vegetable which cannot exist in a wild state; either because, when destroyed by the rigour of the season, he restores it by seeds or by plants derived from a more temperate country; or because he shelters it from the inclemency of the air; or, as is too often the case in our climate, because he is satisfied with the product of the plant, although it should not bring its seeds to perfection. And thus it is that, in the south of Europe, the *Vine*, and *Olive*, and *Orange* trees often vegetate exceedingly well for all the purposes for which they are required, though, if left to themselves, they could not propagate themselves, nor sustain the winter. Thus we see a wide difference in the geography of plants; between those in a state of nature, and those individuals whose growth is artificially encouraged by man.

1050. This, indeed, is a subject closely connected with the *acclimation of plants*, or the power which man is supposed to exert over them in inuring them by degrees to a climate not originally natural to them. This power is, however, denied by very able vegetable physiologists. Mirbel, in particular, declares that he has known many species indeed whose wants have been, to a certain degree, artificially supplied; but not one whose constitution has been changed. "If," he says, "from time to time, exotics mingle themselves with our indigenous tribes, propagate as they do, and even dispute the very possession of the soil with the native inhabitants; this, assuredly, is not the work of man, but it is the climate which dispenses this faculty of naturalisation." Cultivators, however, maintain that seedlings from *Myrtles*, which had ripened their fruit in Devonshire in the open air, are better able to endure the cold of our climate than those seeds perfected by artificial heat, or that have come from the warmer parts of Europe. It is true, the power of so acclimating itself already exists in the vegetable; but it is man that calls it into action, for naturally the

myrtle would never extend itself to our latitudes. Nay, something of the same kind M. Mirbel himself allows, where he says, "When we consider that the *Vine* is cultivated in the plains of Hindostan and Arabia, between the 13th and 15th parallels; that it is cultivated on the banks of the Rhine and Maine, in lat. 51° ; in Thibet, at an elevation above the level of the sea of from 9,000 to nearly 11,000 feet, under the 32d degree of latitude; what astonishes and interests us the most is, not that the vine inhabits countries so remote from one another, or that it grows at so great an elevation above the sea, but that it possesses in so eminent a degree the *property of accommodating itself to different climates*; a property, indeed, much more restricted in a great number of vegetables, which extend from the equator to the tropics on both sides, without ever crossing them; for notwithstanding the greater distance between the 23d degree of southern parallel and the 23d degree of northern parallel, the climatic differences are much less from one tropic to the other than from the plains of Hindostan to the banks of the Maine."

1051. The *distribution of heat at different months of the year* is what we shall find to be of the most importance in regard to vegetable geography. Some climates are eminently uniform; a certain mean temperature is produced by a mild winter and a moderate degree of warmth in summer. This is frequently the case on the sea-coasts, because the extremes of heat are continually modified by the sea; that vast reservoir of nearly equal temperature, which therefore imparts heat in winter and cold in summer, and enables even tropical plants to subsist in some situations of the temperate zone. Such are the western shores of Europe and America, and a great portion of the southern hemisphere. A similar mean temperature may indeed be produced by a combination of very severe winters and very hot summers, as in the great continents compared with islands; or the shores of those continents, or the eastern side of continents, as compared with the western; or the northern with the southern hemisphere; but these two climates, as may be expected, will produce a very different vegetation.

1052. *Annual plants*, which require heat during the summer to ripen their seeds, and which pass the winter, so to say, in torpidity, in the state of grain, indifferent to the intensity of cold*, abound most in those regions where the extremes are the greatest; whilst the *perennial plants*, which can better dispense with the maturing of their seeds, and which are injured by the severities of winter, affect the temperate climates. Of these, again, those kinds which have deciduous leaves accommodate themselves best to unequal temperatures; whilst the individuals on which the foliage remains, or *evergreens*, give the preference to districts where the temperature is more constantly equal.

1053. *Mirbel reckons* that there are about 150 or 160 natural groups or families of plants in the Old World, types of all which exist in the tropical parts of it. Beyond these limits, a great number become gradually extinct. In the 48th degree of latitude, scarcely one half of that number appear; in the 65th, not 40; and but 17 in the vicinity of the polar regions. He further estimates, that within the tropics the proportion of woody species, trees and shrubs, equals, if it does not exceed, that of herbaceous, annual, biennial, and perennial plants. The relative number of the woody species with the herbaceous, annual, biennial, and perennial, decreases from the equator to the poles; but, as an equivalent, the proportion of perennial to annual or biennial plants goes on increasing. Near the extreme limits of vegetation these are, at least, as twenty to one.

1054. *We must, however, by no means conclude* that the same elevation in corresponding degrees of latitude is necessarily suited to the vegetation of the same plants. A number of circumstances may exist to modify the degree of heat at the same elevation. In Switzerland, for example, an investigation of the temperature that prevails in districts situated at only a short distance from each other among the mountains will produce very dissimilar results; and on this subject we find some interesting remarks, extracted from Kasthofer, "*Voyage dans les petits Cantons et dans les Alpes Rhétiennes*," in the first number of the *Foreign Review and Continental Miscellany*. The elevation of the valley of Untersee, we are there told, is the same as that of Gestein; yet the thermometer, in 1822-3, fell only to 8° below zero in the former spot; whereas at Gestein it fell to $10\frac{1}{2}^{\circ}$, and at Berne to 16° . The depth of the valleys influences vegetation; the deeper they are, the more intense is the cold on the summits of the surrounding mountains. Thus, the pine does not thrive on the Brägel, at a height of 5100 feet; whereas it succeeds perfectly, at the same elevation, on the Rhetian Alps, the valleys of the Linth, the Muotta, and Kloen being deeper than those of the latter districts. In like manner, in the valley of the Davos, agricultural produce is certain in places much more elevated than the Bernese valleys, because the latter are deeper. The warm winds from Italy have a perceptible power over the vegetation of the contiguous parts of Switzerland; but the degrees of that influence depend upon circumstances. In the valley of the Inn, barley and flax are cultivated with success at an elevation of more than 5400 feet; whereas at Laret, in the valley of Davos, though the height is only 4900 feet,

* Seeds being, in general, furnished with few organs which abound in moisture, are in a degree insensible to the extremes of heat and cold; whence it arises that, in conveying them from one country to another, they pass through a variety of climate uninjured.

no grain will thrive. Yet these valleys are alike in most respects, and are surrounded by mountains of similar altitudes; they are both sheltered from the north-east wind; their soil is of the same nature; but in the valley of the Inn, the warm winds from Italy are intercepted only by a single chain of mountains, whereas two chains lie between Italy and the valley of Davos: and, besides, the latter being of smaller extent than the former, it admits of the reception of less solar heat. In the Oberland of Berne, an increase in height of 2000 feet diminishes the crop one third.*

SUBJECT. 2. *On the Influence of Light.*

1055. *The influence of the solar light* upon vegetation De Candolle considers to be as important as that of temperature; and although it acts less powerfully upon the geographical distribution of plants, it nevertheless merits a particular notice.

1056. *Light is that agent* which operates in producing the greatest number of phenomena in vegetable life. It determines, in a great measure, the absorption; for plants imbibe less humidity during the night and in darkness. It completely influences the watery exhalations of the green parts of plants; for these parts do not exhale during the night or in obscurity, whilst these exhalations are very considerable during the day, and especially under the direct influence of the rays of the sun. The light affects, in most cases, the decomposition of the carbonic acid; and consequently the deposition of carbon in vegetables, their substance and their growth, the intensity of their sensible properties, and the direction of many organs. It is the principal, and perhaps the only, cause of those singular movements known by the name of the *sleep of plants*; and, lastly, during the absence of light the green parts absorb a certain quantity of oxygen gas. Although these different causes affect all vegetables, yet they are not affected in the same degree.

1057. *Light is more equally distributed than heat* upon the surface of the globe; but its mode of diffusion induces some very important consequences. In the countries situated under the equator, an intense light, since it acts more perpendicularly, influences vegetables nearly equally, during twelve hours each day, throughout the whole year. In proportion as we recede from the equator and approach the poles, the intensity of the more oblique rays gradually diminishes; but in regard to the distribution of these rays, the light is completely wanting during the winter, when the absence of vegetation indeed renders it nearly useless to plants; and it is continued during almost the whole period of vegetation, in such a manner that its lengthened influence compensates wholly or in part for its want of intensity. Thus we see that, independently of what concerns the temperature, plants which lose their leaves can better exist in northern countries, and that those whose vegetation is continued have need of the southern regions. And another beautiful and just remark is made by De Candolle, in reference to the distribution of light; namely, that those plants whose foliage and flowers maintain habitually and constantly the same position, can live in northern climates, where the light is almost continued in summer; whilst it is in the regions of the south that we find, as might naturally be expected, those species which are remarkable for the alternate closing and expanding, or sleeping and waking, of their flowers, a motion which has an intimate connexion with the alternation of days and nights. Thus we see why it is found so difficult in our country to cultivate many of the tropical vegetables, or, at any rate, to bring them to perfection. M. de Humboldt has proved that it is less owing to the absence of heat than to the want of sufficient solar light that the *Vine* does not ripen its fruit beneath the foggy skies of Normandy; and M. Mirbel has satisfied himself that the uninterrupted action of the sun's rays, during a great number of days, is the cause of the astonishingly rapid developement of alpine plants in high northern regions.† Dr. Richardson, too, states that the sugar-boilers in the Canadian forests observe that the flow of sap in the *Sugar Maple* (*Negundo fraxinifolium*) is not so immediately influenced by a high mean temperature as by the power of the direct rays of the sun. The greatest quantity of sap is collected when a smart frost during night is succeeded by a warm sunshiny day.

* The same author, too, mentions a curious fact of vegetation resting upon a basis of ice. The glacier of Roccosecco, which forms one of the branches of the Berneria, has on its summit a nearly horizontal valley filled with ice; and on this the avalanches have brought down masses of earth. This earth produces a number of alpine plants, that afford abundant and nourishing food to the flocks of the inhabitants of Samaden. There are documents which prove that this singular pasture has been used ever since the year 1536.

† "Vegetables," says M. Mirbel, in his *Elémens de Physiologie Végétale*, "when secluded from the light, send out long, thin, and whitish shoots; their substance becomes lax, and without firmness; in fact, they are bleached. The operation of the luminous beams on these organised bodies consists chiefly in separating the constituent parts of water and carbonic acid which they contain, and in disengaging the oxygen of the latter. The carbonic acid, with the hydrogen and oxygen of the water, produce those gums, resins, and oils, which flow in the vessels and which fill the cells. These juices nourish the membranes, and bring them into the ligneous state; a result which becomes more marked as the light is strongest and its action most protracted. Darkness and light produce, therefore, diametrically opposite effects on vegetation. Darkness, by keeping up the softness of the vegetable parts, favours their increase in length; light, by ministering to their nourishment, consolidates them, and arrests their growth. Hence it follows that a fine state of vegetation, such as unites in just proportions size and strength, must depend, in a measure, on the nicely balanced alternation of day and night. Now, the hyperborean plants spring up at a period when the sun is constantly above the horizon, and the light which incessantly acts upon them confirms and perfects them before they have time to attain a considerable degree of length. Their vegetation is active, but soon over; they are robust, but small."

Again, Humboldt assures us, that in all places where the mean temperature is below $62^{\circ} 6'$, the revival of nature takes place in spring in that month whose mean temperature reaches $42^{\circ} 8'$, or $46^{\circ} 4'$. At Cumberland House, Dr. Richardson found vernalion to begin in May, when the mean temperature was only 49° , nearly 3° below that which Baron Humboldt considered necessary for the evolution of deciduous leaves; but he adds, "*the influence of the direct rays of the sun was at this time very great, and the high temperature of the last decade of the month compensated for the first.*" We can imitate the native climes of many of the delicate exotics, as far as regards temperature; and in summer, when our days are long, we see them flourish almost as if they were in their natural situations; but in winter they languish, and often die, especially the more tender species, such as the *Hedysarum gyrans*, and the *humble plant* (*Mimosa pudica*). It is evident that they want that distribution of light which is most congenial to them.

1058. Plants, then, are arranged in their different localities, according to the certain quantity of light which they may require. All those with very watery leaves, which evaporate much, which are of a succulent nature, which, having few pores or organs of evaporation, need a stimulus to determine their action, all which have a tissue abounding in carbon, or which contain very resinous or oily juices, or which offer a great extent of green surface, require much light, and are generally found in exposed places; the rest, according as they are more or less distinguished by these properties, exist either under the slight shadow of bushes, or beneath the more powerful shelter of hedges and walls, or of forests; or, as is the case with many *Fungi*, in caves and darkness. These last are, indeed, destitute of any green colour; but *Mosses*, *Ferns*, and even some evergreens, such as the *Ivy*, flourish best beneath the shade of dense forests, if the trees of those forests have deciduous leaves; and in situations where plants that vegetate only during the summer could scarcely live.

1059. The subject, however, of the *action of light upon vegetation*, has not yet received the attention which it deserves. Many more observations and experiments are required before we can employ it with certainty in connection with botanical geography.

SUBJECT. 3. *On the Influence of Moisture.*

1060. *Water being the vehicle by means of which nourishment is conveyed into the plant*, and, indeed, itself yielding a large proportion or even the whole of the nutriment of many vegetables, it follows that this element is not only of the highest importance in vegetable economy, but one of the causes which affects most powerfully the geographical distribution of plants upon the surface of the globe.

1061. *Those vegetables, in particular, necessarily absorb a great quantity of water*, which have a large and spongy cellular tissue; those which possess broadly expanded soft leaves, furnished with a great number of cortical pores; those having few or no hairs on their surface; those whose growth is very rapid, which deposit but little oily or resinous matter; those of which the texture is not subject to be changed or corrupted by humidity; those, in fine, whose roots are very numerous, generally need to absorb much moisture, and cannot live but in places where they find naturally a large proportion of it. On the other hand, those plants which are of a firm and compact cellular tissue, which have small or rigid leaves, furnished with very few pores, which are abundantly clothed with hairs, of which the growth is slow, and which deposit, during the progress of their vegetation, much oily or resinous matter; those whose cellular tissue is liable to be changed and decayed by too much moisture, and of which the roots are not numerous, require little water, and prefer, for their natural situation, dry places. Great differences, however, are produced, according to the nature of the water that is absorbed; the less it is charged with the nutritive principle, the more necessary is it that the vegetable shall absorb, in a given time, enough to suffice for its support. Again, the more the water abounds with substances which alter its fluidity or transparency, and which, inasmuch as they are solid particles, tend to obstruct the orifices of the pores, or to impede absorption by their viscosity, the less do such vegetables imbibe in a given time.

1062. *The very nature even of those substances dissolved or suspended in the water has a great influence upon the topographical distribution or the locality of plants.* The matters so dissolved are, 1. Carbonic acid. 2. Atmospheric air. 3. Animal and vegetable substances. 4. Alkaline principles or earths. Those plants whose cellular tissue is found to contain much carbon, such as trees producing hard wood, avoid, more than others, the vicinity of waters which are extremely pure, and which contain but little carbonic acid gas. Plants which exhibit much azote in their chemical composition, such as the *Cruciferous Plants* and the *Fungi*, seek those spots where there is much animal matter in solution. Those, again, which present, when chemically analysed, a considerable quantity of certain earthy substances, such as silica* in the *Monocotyledonous Plants*, gypsum in the *Leguminosæ*, &c., will require it in a

* This silica, we know, abounds in the grasses, as well as in other monocotyledonous plants; and M. de Candolle observes, that it is in consequence of its existence in the grasses, &c., and of the comparative insolubility which is the result, that it is preferred by almost all nations of the world for a covering to their houses. The people of the North thus employ straw for that purpose on the same principle that those of the Tropics use the leaves of the palms.

greater or less proportion in the soil where they grow ; and if it does not exist there naturally, the agriculturist must supply it artificially ; and those species which yield, when burned, a more abundant portion of alkaline substances than usual, can only flourish or even live where these matters abound. The species which have need of carbonate of soda will only grow successfully near the sea or saline lakes or springs. Thus the different property of the substances dissolved in the water is evidently one of the many causes which determine the stations of the vegetable species.

SUBJECT. 4. *On the Influence of the Soil.*

1063. The influence of soil M. de Candolle considers as perhaps more complicated than that of the preceding agents. He reduces it to three principal heads : —

1064. (1.) *The soil serves as a means of support to vegetables*, and consequently its *consistence* or tenacity ought to possess, in this point of view, a peculiar fitness for sustaining, in a greater or less degree, plants exhibiting very various forms. Thus, soils composed of blowing sand can only serve as a support to vegetables which are of very humble stature and prostrate growth, so that the winds may not overturn them ; or to trees, furnished with very deep and branching roots, which may attach them into this moveable matrix. The contrary holds good in regard to very compact soils. Small-rooted plants may thus be firmly enough fixed, and they may subsist ; but the very large roots are incapable of penetrating into soils that are very tenacious. The two extremes of these soils present an equally sterile vegetation. Sands which are not sufficiently stationary (as those very remarkable ones on the northern shores of the Moray Firth), water which is subject to very rapid currents, clay of an extremely compact nature, or rocks of great hardness, are equally unfriendly to the growth of plants.

1065. (2.) *The chemical nature of the earths or stones* of which the soil is composed, affects the choice of vegetables, as regards their flourishing in such situations. But this subject, simple as it appears at first sight, is in reality very complicated. For the different earths act upon vegetation by physical circumstances ; as, for example, according as they absorb the surrounding water with more or less facility, retain it with more or less force, or part with it more or less easily. Now, the celebrated Kirwan ascertained by a comparative analysis of earths which were reckoned excellent for the growth of wheat in various countries, that they contain more silica if the climate is more subject to rain, more alumine if the contrary be the case ; in short, that the soil, to be good for any given vegetable, ought to have the power of absorbing more moisture in a dry climate, less in an humid atmosphere : whence it is plain that in different localities the same species of vegetable may be found in different soils.

1066. (3.) *Every kind of rock has a certain degree of tenacity*, and a certain disposition to decompose or become pulverised : whence results the greater or less facility of particular soils to be formed either of sand or gravel, and to be composed of fragments of a nearly determined form and size. Certain vegetables, from causes which we shall presently indicate, will prefer such or such of this sand or gravel ; but the peculiar nature of the soil does not act here immediately ; thus, when we find calcareous rocks which decompose like argillaceous schist, the same species of vegetation is observed. These two considerations are particularly applicable to lichens.

1067. (4.) *Rocks, according to their colour or their nature*, are more susceptible of being heated by the direct rays of the sun ; and consequently they may, in some degree, modify the temperature of a given place ; and influence also, though slightly, the choice of plants capable of succeeding upon them.

1068. But, independently of all these physical causes, it may be asked, whether the *chemical nature of rocks* has any effect upon vegetables ? It is generally considered to be so ; but it must be allowed that this action has been frequently very much exaggerated. Bory de St. Vincent, indeed, has assured us that calamine, or native carbonate of zinc, in the vicinity of Aix-la-Chapelle, is always indicated, to a certainty, by particular plants ; and the fact is confirmed by a little work, since published, called *A Flora of the Environs of Spa*. The *yellow heartsease*, a small variety of the common *Eyebright* (*Euphrasia officinalis*), the *white Campion* (*Silene inflata*), a *Sandwort* (*Arenaria*), a shrubby *Lichen*, a species of *Bromus* (Brome-grass), constitute this poor but constant vegetation. These, however, no doubt, grow in greater abundance and perfection in other soils : the wonder is that they do not altogether perish here ; for even the gallinaceous birds, which eat gravel to triturate their food, die from swallowing fragments of calamine. It must be remarked, in reality, that plants do not often live upon pure rock, but among the decomposed matter of that rock ; that the rocks, even though very circumscribed, often present very different natures : that vegetable mould is not only formed by the rocks which immediately surround it, but also by the admixture of earthy substances carried by the waters, transported by the winds, or by the remains of animals and vegetables which have before existed there. Hence it will be understood how the vegetable earths differ much less in themselves, than the rocks which produce them or serve to support them ; and that the greater number of plants yield, in most

situations, the alimentary earths which are necessary for them. Indeed, after various botanical journeys made through France, M. de Candolle has found nearly the same plants vegetating spontaneously in almost all the different rocky substances. It has been said that the *Bor* (*Buxus sempervirens*) grows only in calcareous soils, and it certainly prefers them; but it is found abundantly in the argillaceous calcareous schistose rocks of the Pyrenees; and it is even seen among the granite of Brittany and upon the volcanic parts of Auvergne. The *Chestnut* has been said to avoid a calcareous country; but there are beautiful chestnuts on both sides of the Lake of Geneva, at the foot of the calcareous mountains of Jura and Chablais.

1069. *Pure magnesia*, M. Carradori has found, by chemical experiment, acts as a poison on most plants; yet M. Dunal, in visiting a portion of the environs of Lunel, where the soil presents a great quantity of almost pure magnesia, found there the same plants as in the surrounding calcareous soil, and the roots flourishing in the clefts of this magnesian rock. Thus we must be careful not to attach too much importance to the nature of the earth, which is frequently acted upon by causes purely physical.

SUBSECT. 5. *Atmospheric Influence.*

1070. *The atmosphere*, taken in its pure state, we know to be composed, at all times, of the same proportions of *azote* and *oxygen*; and in such cases we may suppose its action to be similar upon all vegetables. But the atmosphere also is of different degrees of transparency or density; it holds in solution other matters or substances, which mix with it in certain places, and render it more or less suitable to certain species of plants. In mines, for instance, the quantity of carbonic acid gas, or of hydrogen, may be so great as to preclude vegetation altogether; or to allow only of the growth of such individuals as are very strong and vigorous, or particularly absorbent of these substances. Then, too, the air charged with saline emanations from the sea injures some plants, and on the other hand encourages the developement of such as require carbonate of soda; as may be seen in the valleys of the south of Europe, where maritime plants affording soda may be cultivated at a considerable distance from the ocean, provided that they lie open towards the sea, and are exposed to the winds that blow from it.

1071. *We cultivate in our inland gardens*, languidly and but for a year or two, many of the maritime plants, such as the *Lithospermum maritimum*. The *Nitraria Schoberi* is improved by employing salt where it is grown. Many of the *Statice*s may be, however, easily cultivated, and one of them, the common *Thrift* (*S. Armeria*) even succeeds in crowded towns, whence its English name; yet its native country is either on the shores of the sea or in salt marshes, or upon the summits of the highest mountains.

1072. *The most general influence*, however, exercised by the atmosphere, is its power of containing and parting with moisture, or its hygroscopic action. The atmosphere is habitually charged with moisture; sometimes in such a manner as to be invisible, and then only ascertainable by the hygrometer; at other times visible in a state of vapour or dew; and we find that vegetables in general succeed better in a climate where, at a given degree of temperature, the air is moderately moist, than in another where it is either too much saturated with moisture or too dry. This is a circumstance which cannot well be imitated in the cultivation of plants in the open air: but in our stoves, and especially by the aid of steam, the various degrees of humidity necessary to a vigorous vegetation may be produced to the greatest nicety. Thus, in the magnificent stoves of the Messrs. Loddiges, at Hackney, near London, by an ingenious but simple contrivance, a gently falling dew is imitated; and with what success will best be seen by an inspection of the healthy and beautiful state of those plants which delight in a warm and moist atmosphere.

1073. *The agitation or movement* of the air by winds and other causes exercises some power over vegetation; but we are too little acquainted with this subject to be able to deduce any particular theory from it.

1074. *Of all the atmospheric influences*, the most difficult to reduce to its proper value is that of *density*; or, what is the same thing, the influence of height or elevation above the level of the sea. This M. de Candolle has made the subject of a memoir in the volume of the Society of Arcueil, and we shall here give his general ideas upon it.

1075. *In proportion as we are elevated in the air*, the temperature as well as the moisture continue to diminish; a circumstance which appears to depend upon this, that the rare air has more capacity for heat than dense air. The facts that go to prove that the diminution of the temperature upon high mountains is one of the causes which most affect the distribution of vegetables, are the following:—

(1.) The natural situation of each plant at a determined elevation above the level of the sea is so much the greater in proportion as the country is nearer the equator, and less in more temperate regions; that is to say, the farther we recede from the equator, the greater influence has the exposure upon the temperature.

(2.) In temperate climates, as France, for instance, those plants which are but little affected by temperature, and which grow in all its latitudes, are found also at all those

elevations where the earth is not covered by eternal snows; from the level of the sea to the summits of the mountains. M. de Candolle has detected about 700 examples of this law; the common *Heath*, the *Juniper*, the *Birch*, &c. grow indifferently at the level of the sea, and at a height of 10,000 feet.

(3.) If plants which, according to their nature, avoid either too high or too low a degree of temperature, yet grow at different latitudes, we may observe that it is at heights where the effect of elevation may compensate that of latitude: thus the native plants of the northern plains will be seen to grow upon the mountains of the south.

(4.) Plants which are cultivated upon a large scale are guided by laws which entirely correspond with the preceding: those which are cultivated in various latitudes will grow indifferently at various heights; those which are only found at certain latitudes will extend no farther than to proportional elevations. The *potatoe*, which succeeds so well in our plains, is cultivated in Peru at an elevation of 10,000 feet above the level of the sea: the *olive*, which nowhere passes 44° north latitude, will not grow at a height exceeding 1250 feet.

(5.) The elevation above the level of the sea, when we compare the temperature of the seasons, establishes effects very analogous to those which result from the distance from the equator; so that there is the more analogy between the results on vegetation in the two cases. *In proportion as we rise in a direct line*, it follows, from the lessened density of the air, that the intenseness of the solar light continues to increase; this effect is represented in the line of distances from the equator, because the perpetuity of light during the continuance of vegetation is so much the greater in proportion as the latitude is more elevated.

(6.) *In proportion to the greater height upon the mountains*, so will the hygrometer be seen to indicate a less degree of humidity; the same general effect takes place as we recede from the equator towards the poles.

1076. *On mountains*, covered with perpetual snow, where the plants are constantly moistened with water in a freezing state, those species, to which a warm temperature is unfriendly, will live at inferior heights to those which they brave in the same latitude, when they are not watered from those cold sources.

1077. *It would appear*, therefore, from all these considerations, that the situation or fixed locality of plants at certain heights depends mainly on the fall of the temperature attributable to that elevation. Now, the only purely theoretical point of view, says M. de Candolle, according to which we can comprehend how the rarefaction of the air bears in itself a direct influence upon vegetation, is this; that plants require to absorb a greater or less degree of oxygen gas in their green or their coloured parts. It cannot be doubted that there is a certain point of elevation where the atmosphere becomes too much rarefied to supply the wants of plants; but where this is the case the mountains are always clothed with snow. M. de Humboldt, too, inclines to think that the pressure of the air may act in encouraging and increasing the quantity of evaporation. But we must say that direct experiment is still wanting to confirm these opinions (and this is perhaps unattainable in the present state of science), in order that we may form a conclusive judgment on their value.

SECT. III. *Station and Habitation of Plants.*

1078. *The station and habitation of plants* must next engage a portion of our attention. They are both important: the former implies their situation as regarding local circumstances, and the action of physical causes upon vegetables; the latter implies the geographical position. When we say, that such a plant is found in marshes, on the sea-shore, in woods, or upon mountains, in England, in France, in North America; by the marshes, shore, woods, or mountains, we mean what we here term the *station*; and by England, France, or North America, the *habitation*: such is the sense, at least, in which we shall here use the terms; for in systematic botanical writings the meaning is by no means always thus restricted.

1079. *The seeds of plants*, by varied and beautiful means, are widely dispersed by the liberal hand of nature: whilst some, however, fall upon barren ground, or a soil unfit for the nature of that particular vegetable, others take root in situations, both with regard to the earth and surrounding medium, which are in harmony with their growth, and produce, "some thirty, some sixty, and some an hundred-fold." There are, again, tribes which, under these circumstances, increase so prodigiously that they destroy vegetables of a less vigorous growth, and, to the exclusion of others, appropriate to themselves a great extent of the surface of the earth. Such are termed by M. de Humboldt "*plantes sociales*," plants living in society. In this way, and notwithstanding the extreme poverty of the soil, the *Seaside Sedge* (*Carex arenaria*), the *upright Sea Lyme-grass* (*Elymus arenarius*), and the *Sea-reed* or *Marram** (*Arundo arenaria*), occupy a prodigious surface of our sandy shores, almost to

* The Celtic name of this plant is *Maraim*. A village upon the sea-coast of Norfolk is named Marham, from the circumstance of the great abundance in which the *Arundo arenaria* grows in its vicinity.

the exclusion of other vegetation; their long, creeping, and entangled roots serving to bind the sands together, and thus forming a barrier to the encroachments of the sea. Thus it is with the heaths in our country, where our sterile moors are purple with the blossoms of the heath.

1080. The flowers of the *Gentians* cover, as with a carpet of the most brilliant ultramarine blue, the sides of the alpine hills in Switzerland and the south of Europe. Our fields are often, too often, red with *Poppies*, and the marshes are whitened with the "snowy beard" of the *Cottongrass*, and our pastures with the blossoms of the *Cardamine pratensis*, so that they appear at a distance as if covered with linen laid out for bleaching, whence arises the vulgar English name* of the latter plant. Some of these plants thus living in society are continually striving with their neighbours, till the strongest obtain the victory. Many low perennial and herbaceous vegetables are overpowered by a colony of taller shrubs; such as the *Whin* or *Furze* and the *Broom*: and these in their turns must occasionally give place to trees and shrubs of a larger and stronger growth. Mr. Brown has, however, noticed a curious fact in regard to the *Field Eryngo* (*Eryngium campestre*), and the *Star-thistle* (*Centaurea Calcitrapa*), which cover much cultivated ground upon the continent, that these two engrossers are never mixed together indiscriminately, but that each forms groups of partial masses, placed at certain distances from their rivals.

1081. *On the other hand*, there are plants, which, from the circumstance of their not increasing much by root, or bearing few seeds, or such seeds as from their light and volatile nature are much dispersed, and which are not particular in their choice of soil, do not form groupes, but lie scattered (*Plantes éparses, egrenées, or rares*, of the French).

1082. *The former kind, or "social plants,"* are those which it will be most important for us to consider in relation to Botanical Geography.

1083. *The stations of plants* being thus, as we have already mentioned, liable to the influence of physical agents, it becomes necessary to define them by terms which are calculated at once to point out the places and the circumstances in which they grow. This, however, is a task of no small difficulty; for, without swelling the list to an immeasurable length, it will be impossible to define the various local situations of plants. There are many situations which produce only one or two kinds: for example, the snow, in the highest arctic regions to which our enterprising travellers have attained, has been found to nourish and to bring to the greatest perfection that highly curious vegetable, the *Red Snow* (*Protococcus nivalis*).† The *truffle* (*Tuber cibarium*) is found entirely hid beneath the surface of the earth. Some *fungi* are detected upon the dead horns and hoofs of animals (no plant exists upon living bodies‡), and upon dead chrysalides; and both *fungi* and *mosses* grow on the dung of animals. Paper nourishes the minute *Conferva dendroidea*: the glass of windows, and the glass table of the microscope, if laid by in a moist state for a certain length of time, produce the *Conferva fenestralis*. Wine casks in damp cellars give birth to the *Racodium cellare*: and Dutrochet has detected living vegetables in Madeira wine and in Goulard water, (a solution of Saturn). These, however, and many others that might be noticed, may be numbered among the extraordinary stations, and they principally affect cryptogamic vegetables. In a popular view of the subject, though we cannot altogether omit the notice of such minute yet curious vegetable productions, we shall mainly direct our attention to the more conspicuous plants; and they may be thus divided. 1. *Maritime or saline plants*. These are terrestrial, but growing upon the borders of the ocean or near salt lakes; as the *Saltworts* (*Salsolæ*) and *Glassworts* (*Salicorniæ*), &c. Hence these plants abound in the interior of Africa and the Russian dominions, where there are saltpans, as well as on the shores. 2. *Marine plants*. This tribe is indeed mostly cryptogamic, and comprises the *Algæ*, *Fuci*, *Ulvæ*, &c. The phænogamous, or perfect marine plants, are the *Sea-wracks* (*Ruppia* and *Zostera*), and a few others allied to them. 3. *Aquatic plants*. Growing in fresh water. Both stagnant pools and running streams in various situations, abound in plants. Some are entirely submerged, but in this case, with the rare exception of the little *Awlwort* (*Subularia aquatica*), the flowers rise to the surface of the water for the purpose of fructification.§ 4. *Marsh or swamp plants*. 5. *Meadow and pasture plants*. 6. *Field plants*.

* *Lady's Smock*. Not *Ladies' Smock*. Such plants were in olden time dedicated to Our Lady the Virgin Mary.

† More will be said of this plant when we come to treat of the plants of the high northern regions.

‡ Schouw, indeed, has a tribe of plants which he calls "*Plantæ Epizoa*," attached to living animals. Thus, he says, *Fuci* and other *Algæ* are attached to whales, mussels, and barnacles. But in this case the plants manifestly adhere to a dead portion of the animal; like those vegetables which exist upon the outer and dead part of the bark of trees. I have seen a bee which was brought from Sicily. It had been captured alive, with a substance attached to its head which had all the appearance of a fungus, and from its shape, to that particular genus of *Fungi* called *Clavaria*. Many persons were deceived into a belief that this vegetable substance was growing on the living insect; but an eminent naturalist, well acquainted with the structure of the parts of fructification in the Orchideous plants, immediately detected that the supposed fungus was nothing more than the pollen-mass, which had attached itself to the nose of the bee by means of its glutinous gland, while the busy insect was thrusting its head into the flower to gather its honeyed sweets.

§ Raymond certainly observed, in the Pyrenees, a species of *Crowfoot*, the *Water Crowfoot* (*Ranunculus aquatilis*), producing its flower and fruit wholly under water; but, upon a closer investigation of the phenomenon, he found that in these cases the calyx enclosed a globule of air, with which this important function of fertilisation was performed. The curious aquatic, *Vallisneria spiralis*, has a still more wonderful contrivance

This tribe often includes such as, introduced with the grain sown in those districts, are equally placed there by the hand of man. 7. *Rock plants*, which may include the natives of very stony spots, and such as grow upon walls. Walls, although artificial structures, are known to produce many plants in greater perfection than natural rock; yet we must not suppose that any vegetable is exclusively confined to this habitat. The *Holosteum umbellatum* and *Draba muralis* may be cited as examples of this tribe in England; and amongst mosses, the *Grimmia pulvinata*, *Tortula muralis*, &c. 8. *Sand plants*. 9. *Plants of dry moors*, where our *heaths* (*Ericæ*) abound. These seem to be included among the *plantes des lieux stériles* of De Candolle; a very heterogeneous groupe it must be confessed, and by no means easy to characterise. 10. *Plants which attach themselves to the vicinity of places inhabited by man*. Such are the *Dock*, *Nettle*, &c.; these species follow every where the human footsteps, even to the huts and cabins of the highest mountains; encouraged, perhaps, by the presence of animal substances, and the azote which in such substances is known to abound. 11. *Forest plants*, consisting of such trees as live in society. 12. *Plants of the hedges*, as are many of our climbing plants, the *Honeysuckle*, the *Traveller's joy*, the *Bryony*, &c. 13. *Subterranean plants*. Those that live in mines and caves, and which, though tolerably numerous and important, are yet mostly cryptogamous. One species, a fungus, yields a pale phosphoric light of considerable intensity. 14. *Alpine or mountain plants*, for it is very difficult to draw the limit, and indeed they will depend much upon latitude. A plant which grows upon a hill of inconsiderable elevation in Norway, Lapland, and Iceland, will of course inhabit the loftiest Alps of the south of Europe. Again, upon mountains that have no perpetual snow lying on them, alpine plants will be found much higher than on such as have continued streams of cold snow-water descending, which affects the state of the atmosphere at much lower regions. 15. *Parasitic plants*, such as the *Misseltoe*, the various species of *Loranthus*, &c., and that most wonderful of all vegetable productions, the *Rafflesia Arnoldii*: these, as their name implies, derive nourishment from a living portion of the vegetable to which they attach themselves. This is the case, too, with many *Fungi* which subsist upon the living foliage of plants; some exclusively on the upper, others as invariably on the lower side of these leaves; and, lastly, the name of 16. *Pseudo-parasites* has been given to a very extensive tribe, which subsist upon the decayed portions of the trunk or branches of the trees to which they are attached, as many of the *Lichens*, *Mosses*, &c.; or which are simply attached by the surface of their roots to tropical trees, obtaining no nourishment from them, but from the surrounding element. Among this number may be reckoned that numerous and singular family of the *Orchideæ*, called, from their nature and property, "*air plants*." Greatly as this list might be swelled, we shall find that even here there is a gradation and an approximation of one tribe to another; but these are amply sufficient for our purpose.

1084. We have been able to account in some measure for the stations of plants, affected as these are by local circumstances; but the study of the succeeding part, which refers to their *habitations*, considered in their most extensive scale, for instance, as belonging to certain regions or countries, we shall find to be much more difficult; and we must frequently be content to study and to admire the amazing variety of vegetable forms which the beneficent hand of nature has scattered over the different parts of our world, without being able to account for these important phenomena. In New Holland we find, almost exclusively, all the species of *Banksia*, *Goodenia*, and *Epacris*, and the curious *Acaciæ* without leaves, but with petioles so much enlarged as to amuse the shape and perform the functions of leaves. At the Cape of Good Hope, the *Fig Marigolds* (*Mesembryanthema*), the *Stapeliæ*, the numerous kinds of *Ixia*, *Gladiolus*, *Pelargonium*, and *Protea* abound. The *Aurantiaceæ*, the family of plants to which the *Orange* and *Lemon* belong, are of Asiatic origin; as the *Camellia* and *Thea* are of Chinese. Those curious plants, the *Mutisiæ*, the various species of *Fuchsia*, the *Cinchonæ* or *medicinal barks*, the *Cacti*, are all peculiar to South America. If a few of them are found in other countries, such circumstances are of very rare occurrence, and do not overturn the general laws for the exclusive existence of many plants in certain countries. We have in the temperate parts of Europe one species of *Ixia*, one of *Gladiolus*, and in the north of Africa and south of Europe a few kinds of *Fig Marigold*. Within the tropics the genera of plants, throughout Asia, Africa, and America, are similar, but rarely are the species the same. This rule nearly holds good on the opposite continents in temperate climates. We have the *Oriental Plane* (*Platanus orientalis*) in the old world, and the Americans have the *Occidental Plane* (*P. occidentalis*). Even in the two hemispheres, in similar parallels of latitude, the genera of plants have a great affinity: the southern extremity of the great continent of

for bringing the male and female flowers in contact. The plant is diœcious. The female flower is attached to the parent plant by means of a very long stalk, spirally twisted like a corkscrew, so that when it is in perfection, it rises to the surface by the untwisting of the stalk. The male flowers, upon a separate plant, are almost sessile, borne on a very short straight stem, which never could reach the surface without detaching themselves from the plant. This they do at the proper season; they float upon the top of the water along with the female flowers, scatter their pollen, and die. The female blossoms, on the contrary, by the spiral twisting of their stalks, retire, and ripen their seeds under water.

America has many in common with the north of Europe; and the plants of our regions, transported thither, succeed extremely well.

1085. *To what extent plants migrate*, unaided by man, it is not easy to say; but that such migration is going on, by various means and causes, cannot be questioned. Islands which lie near to continents, and which evidently appear at one period to have been joined with them, as England for example, although they may contain a vegetation similar to that of the neighbouring continental shores, have always a smaller number of species; and this can only be accounted for by the interruption which straits or seas occasion to the progress of the seeds.

1086. *The Field Eryngo* (*Eryngium campestre*), to which we have already alluded, the *Venus's looking-glass* (*Campanula Speculum*), and many other plants of France and Germany, seem to stop at the line formed by the sea in approaching our shores; yet these, and many other vegetables of France, reach a limit upon the same continent more northern than any part of England.

1087. *The transmigration of plants* may be reckoned to be facilitated by the following causes. 1. *The sea and its currents*, but to a very limited extent; for if the seed be of such a nature that the water penetrates its integuments and reaches the embryo, life is destroyed. Yet to such a distance are they carried by this medium, that upon the coasts of Britain, of Iceland, and Norway, the seeds of the West Indies are frequently cast, and it is said sometimes even in a fit state for vegetation. 2. *Rivers*, by the continual movement of their waters, convey many plants to a considerable distance from their original place of growth; and the banks of streams are generally adorned with a vegetation of a more varied kind than the districts remote from them. Thus, too, the different species of *Saxifrage* and other alpine plants are, in mountainous regions, brought down from the higher situations, and flourish in the valleys. 3. *Winds*, which waft the light, winged, and pappose seeds to immense distances, and by means of which they are widely dispersed. 4. *Animals*, which, in wandering from place to place, often carry on their coats those seeds which have hooked bristles, &c. 5. *Birds*, which, swallowing berries and other fruits, pass the seeds in a perfect state, and, it is even said, sometimes better fitted for germination than before. In this manner the seeds are often deposited in the places necessary for their growth, and to which they could not otherwise have reached; of which a familiar instance is found in the *Misseltoe*.

1088. *Man is however the most active agent in the dispersion of plants*, and we must not overlook the important consequences. Sometimes, indeed, the causes are accidental, but more frequently intentional. The shipwreck of a vessel on the island of Guernsey, having some bulbs on board from the Cape of Good Hope, caused a plant to propagate in the sands upon the shores of that mild climate, to which has been since given the name of *Amaryllis Sarniensis* or *Guernsey Lily*, and a branch of trade of some importance is carried on in the sale of this very root. At Buenos Ayres, a species of *Artichoke* (*Cynara Cardunculus*) has increased so much by seeds imported from Europe, that Mr. Head, in his amusing "*Sketches of a Journey across the Pampas*," &c. tells us that "there are three regions of vegetation between Buenos Ayres and the base of the Cordilleras; a space of 900 miles: the first of which is covered, for 180 miles, with clover and *thistles*. This region," the author continues, "varies with the seasons of the year in a most extraordinary manner. In winter, the leaves of the thistles* are large and luxuriant, and the whole surface of the country has the rough appearance of a turnep field. The clover in this season is extremely rich and strong; and the sight of the wild cattle grazing in full liberty on such pasture is very beautiful. In spring the clover has vanished, the leaves of the thistles have extended along the ground, and the country still looks like a rough crop of turneps. In less than a month the change is most extraordinary; the whole region becomes a luxuriant wood of enormous thistles, which have suddenly shot up to a height of ten or eleven feet, and are all in full bloom. The road or path is hemmed in on both sides; the view is completely obstructed; not an animal is to be seen; and the stems of the thistles are so close to each other, and so strong, that, independent of the prickles with which they are armed, they form an impenetrable barrier. The sudden growth of these plants is quite astonishing; and though it would be an unusual misfortune in military history, yet it is really possible that an invading army, unacquainted with this country, might be imprisoned by these thistles before it had time to escape from them. The summer is not over before the scene undergoes another rapid change: the thistles suddenly lose their sap and verdure, their heads droop, the leaves shrink and fade, the stems become black and dead; and they remain, rattling with the breeze, one against another, until the violence of the pampero or hurricane levels them with the ground, when they rapidly decompose and disappear, the clover rushes up, and the scene is again verdant."

1089. *The strong-scented Everlasting* (*Elichrysum fœtidum*, vid. Bot. Mag. t. 1987), a

* From specimens in our Herbarium, we have ascertained that this *thistle* is the *Cardoon* (*Cynara Cardunculus*), introduced no doubt from Europe as an article of food, but now growing wild, useless, and pernicious.

native of the Cape of Good Hope, has found a soil and climate equally suited to its growth on the shores of Brest, where it covers a great portion of the sands, to the exclusion of the aboriginal natives of the soil. *Wheat* is supposed to be indigenous to Barbary. The *potatoe*, first found in South America, is now cultivated all over the world. *Rice*, from Asia, is grown to an immense extent in America, &c. ; these, and many other plants similarly circumstanced, which we could mention, together with those that adorn our gardens, often owe their wide diffusion to having escaped into uncultivated places, and become to a certain degree naturalised there.

1090. But *there are limits to migration*, for some of which we can account, and for others we cannot. Even many of our garden plants, which, escaping by accident, or designedly placed in uncultivated spots so as to appear wild, have only for a time maintained a languid existence, and then have disappeared altogether. Thus we know that the beautiful *Gentianella* (*Gentiana acaulis*) cannot have a title to a place in the British Flora, nor can some others, which are mere outcasts from gardens. Some plants are wholly confined to particular spots, and can be found nowhere else. The *Tree-Pink* (*Dianthus arboreus*) grows still on the single rock in the island of Crete, where Prosper Alpinus first detected it; and the *Double Cocoa-nut* of the isle Praslin, one of the little groupe of islands called the Seychelles, notwithstanding the annual migration of its nuts for many thousands of miles, has never established itself in any other place. Nature has planted the *common Thrift* (*Statice Armeria*), the *Scurvy Grasses* (*Cochlearia anglica* and *danica*), and the *Rose-root* (*Rhodiola rosea*), in rocky and stony places, upon our shores and on the tops of the highest mountains; yet these plants are never found in any intermediate places.

1091. *The visible obstacles to the migration of plants are —*

(1.) *The sea*, which, though we have introduced as a means of extending the habitations of plants, is yet a far greater impediment, by the injury it does to the seeds, and the difficulty of their being conveyed to distant countries in a sufficiently short time to prevent the natural death of the seed. It must be observed, too, that the greater number of seeds have a specific gravity heavier than that of water when in a living state. The *Double Cocoa-nut*, when found floating, has always lost its vegetative property. The living nut is immensely heavy, and would inevitably sink.

(2.) *Dry and burning deserts*. These, in spite of their oases, which have been happily assimilated to the isles of the ocean, prove a powerful obstacle to the transport of seeds. Thus, those districts of Africa which are separated from one another by the scorching sands of Sahara exhibit a great dissimilarity in their vegetation. The plants of Morocco and the northern parts of Africa have little resemblance to the indigenous growth of Senegal; whilst the affinity of the vegetables brought by Caillaud from Upper Egypt to those collected by Palisot de Beauvois in Oware and Benin would in themselves lead to the conclusion that no very great and continued deserts intervene between these far distant countries.

1092. *Mountain ranges*. The barriers which these present would almost be insurmountable, were it not for the defiles which here and there occur, forming passages for men and animals, as well as for plants. Thus, the plants on the Italian side of the Alps are quite different from those on the Switzerland side; those of the Spanish Pyrenees from those of the French Pyrenees; and it was a subject of peculiar regret to the enterprising Drummond, when he reached the summits of the Rocky Mountains in North America, that his commission did not allow him to penetrate farther into the western side of that great continent, where he found, every step he took, a vegetation very different from what had been presented to him by the eastern side.

1093. *A knowledge of the Natural Orders of plants* is in no department of botany so important as in treating of their geographical distribution. The system of Linnæus, or the Artificial Arrangement, does not, as we know, regard the habits and affinities of vegetables, but simply and beautifully points out to us, by certain characters, the means of arriving at the knowledge of any given species. The natural method, which owes so much to the labours of Jussieu, Decandolle and Brown, has a higher object in view, that of grouping plants together according to their natural affinities; and by such an arrangement we are often led to other and very important results. The primary divisions of the Natural Method are, first, ACOTYLEDONES, or plants which have no cotyledons to the seed: these are synonymous to the Cryptogamia, and include the *Mosses*, *Lichens*, *Sea-weeds*, *Fungi*, *Ferns*, &c. ; secondly, MONOCOTYLEDONES; those whose seeds have one cotyledon, such as the *Grasses*, *Liliaceous Plants*, the *Rushes*, *Sedges*, the *Palms*, &c. ; and, thirdly, DICOTYLEDONES, or the plants which have two or rarely more cotyledons to the seed, such as our *Shrubs* and *Trees*, and very many *Herbaceous Plants*. Each of these possesses external characters which, though not very easily defined in words, yet cannot fail to strike the observer who devotes his attention, even for a little while, to the subject; and we find that, in a great proportion of instances, they have not only a peculiar station, but that their geographical distribution is different.

1094. *The ACOTYLEDONOUS plants increase in number in proportion to the other great classes*, as we recede from the equator to the poles; with the exception, however, of the *Ferns*. The latter abound more within the tropics than any where else: not, however, so much in

open plains as in the sheltered, moist, and hilly countries; so that their maximum is in the mountainous part of the tropics. The island of Martinique afforded to the Abbé Plumier a rich and abundant harvest of ferns; and some isles of small extent are said to have one third of their vegetation composed of this kind of plants.

1095. Among the MONOCOTYLEDONOUS Plants, the *Palms* are exclusively confined to the tropics: the *Liliaceous plants* abound there and in the warm zones; the three families of *Grasses*, *Sedges* (Cyperaceæ), and *Rushes* (Junci), present some important differences in regard to a comparison with the phænogamous or flowering plants. The disparity between these latter and the *grasses* is not great in each of the zones; whilst the two other families, the *Cyperaceæ* and *Junci*, diminish near the equator and increase towards the north. Nevertheless, there are exceptions to this rule; for the *grasses* are very rare upon the coasts of Greenland. In what we have now said, we allude to the *grasses*, &c. in a wild state; having no reference to those regions where so many of the grass tribe, as the *Wheat*, *Barley*, *Oat*, *Maize*, *Rye*, *Rice*, &c., are found simply in a state of cultivation.

1096. The DICOTYLEDONOUS plants are the most extensively distributed, and we must offer some further remarks upon them. The *Compound* or *Syngenesious plants* (Compositæ), as every one knows, form a very extensive natural family. They are diffused throughout the whole earth, but they are most abundant in the temperate and tropical climates. Fewer, however, of them are found in the warm regions of equinoctial America than in the sub-alpine and temperate districts of the same country. At the Congo and Sierra Leone in Africa, in the East Indies and New Holland, they exist in comparatively smaller numbers than in other regions situated in similar parallels, but which afford situations more congenial to their growth. Again, in the frozen zone, in Kamtschatka and Lapland, the relative proportion of plants of this family is one half less than in the temperate climates.

1097. The *Leguminous plants* (to which the *Pea*, the *Bean*, &c. belong, and such as bear papilionaceous flowers,) abound most in the equinoctial regions: they diminish gradually in each hemisphere in diverging from the equator, except indeed in certain countries where particular genera, by the multiplicity of their species, give a peculiar feature to the vegetation, as in Siberia and the vast provinces of Russia, where so many *Astragali* or Bitter-vetches are found.

1098. Mr. Brown has judiciously separated the natural order of *Rubiaceæ* into two groups: those with verticillate leaves and no stipules (the *Stellatæ* of Linnæus), to which belong our *Goosegrass* (*Galium*), *Madder* (*Rubia*), &c., and which are almost peculiar to the temperate zones; and the true *Rubiaceæ*, with opposite pairs of leaves, and two opposite stipules (which are in fact abortive leaves, and thus show their affinity with the *Stellatæ*), to which belong the real *medicinal barks* (or *Cinchonæ*), and some other nearly related plants possessing similar virtues: these latter are almost wholly confined to the equinoctial regions.

1099. The two well known and extensive natural families, the *Umbelliferous* and *Cruciferous plants*, are very rare in the tropics, if we except the mountains. They abound in the south of Europe, and especially about the valley or basin of the Mediterranean.

SECT. IV. View of Botanical Regions.

1100. To divide the globe into botanical regions or districts will not be difficult, seeing that certain countries possess a peculiar vegetation, and that numerous impediments prevent emigration; seeing, too, that certain forms or tribes are incompatible with certain climates. M. De Candolle has constituted twenty of those regions; but although each is, to a certain degree, peculiar in its vegetable productions, it would require more space than we can devote to such a subject to characterise them. We must, therefore, content ourselves with giving a bare list. 1. *Hyperborean region*. This district includes the northern extremity of Asia, Europe, and America; and gradually merges into the following. 2. *European region*; comprising all Europe, except the part bordering upon the pole, and the southern districts approaching the Mediterranean. To the east it extends to the Altaic mountains. 3. *Siberian region*, comprehending the great plains of Siberia and Tartary. 4. *Mediterranean region*; comprising all the basin of this great inland sea; that is, Africa on this side the Sahara, and that part of Europe which is sheltered from the north by a more or less continued range of mountains. 5. *Oriental region*; thus called relatively to southern Europe, and containing the countries bordering upon the Black and Caspian Seas. 6. *India*, with its archipelago. 7. *China*, *Cochinchina*, and *Japan*. 8. *New Holland*. 9. *The Cape of Good Hope*, or southern extremity of Africa, beyond the tropics. 10. *Abyssinia*, *Nubia*, and the *Mozambique Coast* (imperfectly known). 11. *Equinoctial Africa*; viz. the neighbourhood of the Congo, the Senegal, and Niger. 12. *The Canary Isles*. 13. *The United States of North America*. 14. *The Western and Temperate Coasts of North America*. 15. *The West Indian Isles*. 16. *Mexico*. 17. *Tropical South America*. 18. *Chili*. 19. *Southern Brazil* and *Buenos Ayres*. 20. *The Straits of Magellan*.

1101. Many of the productions of these regions will be considered somewhat at large in other parts of this work; and we shall conclude our introductory sketch of Botanical Geography by a notice of Professor Schouw's *Phyto-Geographic* or General Botanical Division of the

Globe. This is illustrated by a map, which accompanies this memoir. Unlike M. De Candolle, Professor Schouw characterises the regions by the most remarkable feature of their vegetation, adopting commonly used geographical terms only where he conceives that a certain division of the earth ought to constitute a distinct region, but is not sufficiently acquainted with its productions to determine and define their forms. He makes the characteristic feature of his regions to depend on these facts: first, that at least one half of the species should be peculiar to that region; secondly, that at least a quarter of the genera should belong exclusively to it, or at least have there a decided maximum, so that their species in other districts might merely be considered as their representatives; and, thirdly, that individual families of plants be either peculiar to the region, or else have their *maxima* there; nevertheless, when this last characteristic is wanting, while the difference in genera and species is very considerable, it may yet be admitted as a region.

Professor Schouw in this manner reckons twenty-two regions: —

1102. (1.) *Region of Saxifrages and Mosses, or the Alpine Arctic Flora.* — This corresponds with De Candolle's first region, and comprehends all the countries within the polar circle; namely, Lapland, the north of Russia and Siberia, Kamtschatka, Canada, Labrador, Greenland, and Iceland; but Professor Schouw adds to it, with much propriety, part of the Scottish and Scandinavian mountains, as far as they fall within the alpine region, as also the mountains in the southern and central parts of Europe, inasmuch as they are related to the alpine regions. It is characterised by the abundance of *mosses* and *lichens*, the presence of the *Saxifrages*, *Gentians*, *Chickweed* tribe (*Alsineæ*), *Sedges*, and *Willows*; an entire absence of tropical families; a considerable decrease of the peculiar forms of the temperate zone; by the forests of *beech* or *fir*, or else the total want of trees; the scarcity of animals, and the prevalence of *cæspitose* plants, whose blossoms are large in proportion, and generally of a pale colour.

1103. (2.) *Region of the Umbelliferous and Cruciferous plants.* — This tribe takes in the whole of Europe, except what belongs to the preceding division, from the Pyrenees, the mountains of the south of France, of Switzerland, and the north of Greece, to the greater part of Siberia, and the country about Mount Caucasus. Schouw has characterised it by the *cruciferous* and *umbelliferous* plants, because they form a larger portion of the total number than any other kinds, and because it may thus be best separated from the vegetation of North America in the same parallel. It is not easily distinguished from the next region; but it may be said of it, that *Fungi* abound more, that the *Rosaceous* family and the *Crowfoots* (*Ranunculaceæ*), the *Amentaceous* and *Coniferous* tribes (*Pines*), form rather a large proportion; that it bears a resemblance to many of the polar forms, especially in the abundance of its *Sedges* (*Cyperaceæ*); that its meadows are most flourishing, and that almost all the trees are deciduous in winter. In the northern part of this region, the *Cichoraceæ* (a tribe of the *Compositæ* or syngenesious plants, including the *Endive*, *Lettuce*, *Dandelion*, &c.) much prevail; while in its southern division, or in northern Asia, the *Cynarocephalæ* (*Artichoke* and *Thistle* tribes), together with the *Butter-vetches* (*Astragali*), and *Saline plants* (*Sea-worts* and *Glass-worts*), seem to have their maximum.

1104. (3.) *Region of the Labiate flowers and Caryophylleæ* (to which the *Pink*, the *Catch-fly*, the *Sandworts*, &c. belong); or the *Mediterranean Flora.* — This is bounded on the north by the Pyrenees, the Alps of Switzerland and of the south of France, and the north of Greece, and thus includes the three peninsulas of southern Europe, namely, Spain, Italy, and Greece; on the west by Asia Minor and its islands; on the south it takes in Egypt and all the north of Africa as far as the deserts; and, lastly, it includes the Canary Islands, Madeira, and the Azores. It is marked especially by the two families above mentioned, which are much rarer both to the north and south of the countries just enumerated, and in the corresponding parallels in North America. The *Compositæ*, the *Stellatæ* (*Goosegrass*, *Madder*, &c.), and the rough-leaved plants (*Asperifoliæ*), are here in considerable numbers, as well as in the similar latitudes. A few tropical plants, or individuals allied to them, now appear; one or two *Palms*, the *Laurels*, the *Arum* tribe, the *Terebinthaceæ* (*Pistacia*, &c.), some tropical grasses and true *Cyperaceæ*. *Nightshades* (*Solanææ*), *Leguminous* plants, the *Mallow* and *Nettle* tribes, and the *Spurges* (*Euphorbiaceæ*), increase; *Evergreens* are numerous; vegetation never entirely ceases, but verdant meadows are more rare. This region may be subdivided into provinces: of the *Cisti*, Spain and Portugal; of the *Sage* and *Scabious*, the south of France, Italy, and Sicily; of the shrubby *Labiatæ*, the Levant, Greece, Asia Minor, and the southern part of the Caucasian country; and of *Houseleeks* (*Sempervivæ*), the Canary Isles, probably also the Azores, Madeira, and the north-west coast of Africa. Many *Sempervivæ*, some succulent plants, *Spurges*, and *Cacaliæ*, characterise especially this province.

1105. (4.) *The Japanese region.* — The eastern temperate part of the old continent, namely, Japan, the north of China, and Chinese Tartary, probably forms a peculiar region; but we are too little acquainted with the botany of these countries to admit it with certainty, and still less are we able to define correctly the characteristics of its Flora. Of the 358 genera found in Japan, 270 occur in Europe and the north of Africa, and about the same number in North America; so that its Flora seems to occupy a middle place between those of the old

and new worlds. Its vegetation, indeed, approaches more to the tropical than to the European; for we meet with the *Cycas* family, the *Scitamineæ* (to which belong the *Ginger*, *Cardamom*, &c.), the *Bananas*, the *Palms*, the *Anonæ* or *Custard-apples*, and the *Sapindaceæ*; so that there is a considerable affinity, as might be expected from its situation, to the flora of India. The families of the *Buckthorns* (*Rhamni*) and *Honeysuckles* are found in a relatively considerable number, and they exhibit some peculiar genera; thus, perhaps, this region might be correctly termed that of the *Rhamni* and the *Caprifoliaceæ*.

1106. (5.) *Region of the Asters and Solidagos* (Michaelmas-daisies and golden-rods).—The eastern part of North America, with the exception of such as belongs to the first or arctic district, comprehends without doubt two regions; for amongst 417 genera in Walter's Flora of Carolina, 117 are wanting in Barton's Flora of Philadelphia. The northern divisions of the United States have, indeed, but few genera which do not occur also in the southern; but this only shows that a similar relation exists here to what takes place between the north and south of Europe. The southern region will include Florida, New Orleans, Georgia, and Carolina; the northern contains the other states of North America. What characterises this region is (besides the number of species of the genera *Aster* and *Solidago*), the great variety of *Oaks* and *Firs*; the very few *Cruciferae* and *Umbelliferae*, *Cichoraceæ* and *Cynarocephalæ*; the total absence of the genus *Erica*, and the presence of more numerous species of the allied family of *Vaccinium* (Whortleberries) than are to be met with in Europe.

1107. (6.) *Region of Magnoliæ*.—This, which comprises the most southern parts of North America, is separated from the preceding region by the number of tropical forms which here appear, and which show themselves more frequently than on the similar parallel of the old continent (such, for instance, as the *Scitamineæ*, *Cycadeæ*, *Anonaceæ*, *Sapindaceæ*, *Melastomeæ*, *Cacti*, &c.). From the old world, too, in corresponding latitudes, it is still further distinguished by a smaller proportion of *Labiatae* and *Caryophyllæ*; and by having more trees of broad shining foliage and splendid blossoms (the *Magnolias*, the *Tulip-tree*, the *Horse-chestnut*, &c.) and with pinnated leaves (the *Gleditschiæ*, *Robinia*, *Acaciæ*, &c.).

1108. (7.) *Region of the Cacti, Peppers, and Melastomas*: a very extensive region, including the lower districts of Mexico, the West Indies, New Granada, Guiana, and Peru, perhaps also a part of Brazil; in short, all intertropical America. The three families here mentioned appear peculiarly to characterise these countries; for the first belongs exclusively to America, and of the other two there exist comparatively few species out of these districts. *Palms*, the *Rubiaceæ*, the *Solanæ* (in which are classed the *Nightshades* and *Potatoes*), the *rough-leaved plants* (*Boraginæ*), the *Passion-flowers* and *Compositæ*, are here very common. It may admit of several provinces, as that of the *Ferns* and *Orchideæ* (in the West India islands); of the *Palms* (the continent of South America). Brazil ought certainly to constitute a peculiar province, if indeed it be not a distinct region; and the works of Spix and Martius, St. Hilaire, the Prince de Neuwied, &c., will soon enable us to characterise its vegetable forms. The *Melastomæ* and *Palms* appear to belong to the more numerous inmates of this region.

1109. (8.) *Region of the Cinchonæ* (or Medicinal Barks).—It appears from Humboldt's works that the middle districts (such at least in respect to their altitude) of South America should form a distinct region from that last mentioned, as they differ considerably from the low lands; and the name now proposed seems to be characteristic of their vegetation, at least of Peru and New Granada, though certainly not of Mexico, where the species of *Cinchona* are wanting.

1110. (9.) *Region of Escalloniæ, Vaccinia* (Whortleberries), and *Winteræ* (Winter's Barks).—These, according to Humboldt, occupy the highest parts of South America. Besides the plants mentioned, there belong to this region many species of *Lobelia*, *Gentian*, *Slipperwort* (*Calceolaria*), *Sage*, several European genera of *Grasses*, *Brome*, *Festuca* and *Poa*, the *Cichoraceæ*, as *Hypochaeris* and *Apargia*; as well as the more strictly speaking alpine plants (*Saxifrages*, *Whitlow-grasses*, *Sandworts*, and *Sedges*). Perhaps also those parts of the high lands where the species of *Oak* and *Fir* flourish belong to the same region, though in all probability they constitute a peculiar province.

1111. (10.) *Chilian region*.—It appears that Chili should form a distinct region; for amongst the genera which appear there, not one half are found in the low districts of South America. Its character, perhaps, most resembles that of the mountainous country, in its *Slipperworts*, *Escalloniæ*, *Weinmanniæ*, *Bæa*, *Bellflowers*, and *Buddleæ*; but yet the difference is scarcely sufficient to constitute it a province. The Flora of this country appears to be essentially distinct from that of New Holland, the Cape, and New Zealand; though an approach to them is observable in *Goodenia*, *Araucaria* (Chilian pine), the *Protea* family, *Gunnera*, and *Ancistrum*.

1112. (11.) *Region of arborescent Compositæ* (syngenesious plants with tree-like stems).—This takes in Buenos Ayres, and in general the eastern side of the temperate part of South America. It has been already remarked, that the Flora of this district of the world agrees to a considerable degree with that of Europe: amongst 109 genera, 70 are likewise European, and 85 in the north temperate zone. On the other hand, it differs considerably from the Floras of

the Cape and of New Holland, for the *Proteas*, the *Myrtle* tribe, and the *Mimosas* are either wholly wanting, or are seen but sparingly; and there are no *Epacrideæ*, *Heaths*, *Irideæ*, *Mesembryanthema*, or *Geraniums*. Nor can it be compared with the Flora of the north-west coast of America; for amongst 189 genera mentioned, only 35 are found in Chili. The characteristics of this region seem to lie in the great number of *Arborescent Syngenesiæ* (particularly of the sub-family *Boopideæ*), which, however, do not exclusively appertain to it, but are also seen at the Cape.

1113. (12.) *Antarctic region*. — This includes the countries near the Straits of Magellan. There is a considerable affinity between the vegetation here and what is seen in the north temperate zone; for, amongst 82 known genera from thence, there are 59 of them which have species in the northern hemisphere. The arctic polar forms also appear, such as *Sedges* (*Carices*), *Saxifrages*, *Gentians*, *Arbutus*, and *Primroses*. Some resemblance to the highlands of South America and to Chili is also shown in the *Slipperworts*, *Ourisia*, *Bæa*, *Bolax*, *Wintera*, *Escallonia*; to the Cape, in the genera *Gladiolus*, *Witsenia*, *Gunnera*, *Ancistrum*, *Oxalis*; and to New Holland, in *Proteaceæ* and *Mniarum*.

1114. (13.) *Region of New Zealand*. — This well deserves to be characterised as a separate region, although its vegetation be a mixture of what prevails on the nearest continents, as South America, Southern Africa, and New Holland. It has, in common with South America, *Ancistrum*, *Weinmannia*, *Wintera*; with Southern Africa, the *Fig Marigolds*, *Gnaphalium*, *Xeranthema* (Everlastings), *Tetragonia* (the famous New Zealand Spinach), *Woodsorrel*, and *Passerina*; and with New Holland, the *Epacris*, *Melaleuca*, *Myoporum*; with both the latter, the families of *Proteaceæ* and *Restiaceæ*: some species also are common both to New Holland and Van Diemen's Land, for instance *Mniarum biflorum*, *Samolus littoralis*, *Gentiana montana*; the first also a native of the Straits of Magellan.

1115. (14.) *Region of Epacrides and Eucalypti*: comprehending the temperate parts of New Holland, together with Van Diemen's Land. — This region is very marked. The families of *Stackhouseæ* and *Tremandreaæ* are quite peculiar to New Holland, the *Epacrideæ* nearly so. *Proteaceæ*, *Acaciæ*, *Aphyllæ*, and the greater number of the *Myrtle* family (especially of the genera *Eucalyptus*, *Leptospermum*, *Melaleuca*); the *Stylideæ*, *Restiaceæ*, *Casuarineæ*, *Diosmeæ*, separate it from other regions. The tropical part of New Holland, according to Brown, can hardly be united to this, but must be either a particular region, whose Flora resembles that of India, or else a province of this latter region.

1116. (15.) *Region of Fig-Marigolds* (*Mesembryanthema*) and *Stapelias*. — This comprehends the southern extremity of Africa, the Flora of which is distinguished by a high degree of peculiarity. By the families *Proteaceæ*, *Restiaceæ*, *Polygalæ* (Milkworts), *Diosmeæ*, it may be recognised from most others, except New Holland, and from this it is distinguished by the two numerous genera *Mesembryanthemum* and *Stapelia*, and by the family *Ericææ*, which is here more abundant than any where else. Further characteristics of this region may be found in the many *Irideæ*, *Geraniæ*, *Oxalideæ*, and the extremely large proportion of *Compositæ*. On the other hand, there exist in this district, as in New Holland, but very sparingly, those peculiar forms of the northern temperate zones, the *Cruciferaæ*, *Ranunculaceæ*, *Rosaceæ*, *Umbelliferaæ*, *Caryophylleæ*.

1117. (16.) *Region of Western Africa*. — We are only acquainted with Guinea and Congo, the vegetation of which, as we have already remarked, possesses but few peculiarities, and is a mixture of the Floras of Asia and America, though most resembling the former. The American tropical families of *Cacti*, *Peppers*, *Palms*, *Passion-flowers*, are either absent entirely, or they occur in small numbers. *Leguminosæ* are more numerous than in America. Above two thirds of the genera and some of the species of Guinea are found also in the East Indies. On the other hand, this region approximates to America, in possessing many *Rubiaceæ*, as also in the genera *Schwenkia*, *Elais* (a palm), *Paullinia*, *Malpighia*, and several more which are wanting in Asia, and in several species which it has in common with America. A considerable proportion of *Grasses* and *Sedges* (*Cyperaceæ*), with the peculiar genus *Adansonia* (the Baobab, which is the largest known tree in the world), belong to the characteristics of this country. The interior of Africa is unknown to us.

1118. (17.) *Region of Eastern Africa*. — Of the coast of this side of Africa and the adjacent islands our knowledge is imperfect. We are tolerably acquainted with the islands of Bourbon and France; of Madagascar we know but little; and of the east coast itself scarcely any thing. The Flora of the two first-named islands has a considerable resemblance to that of India. Amongst 290 known genera, 196 of them (equal to two thirds) are found also in India; and of the species, not a few are likewise Indian; many of these, however, may have been introduced by the constant intercourse that takes place between these two parts of the globe. The genera *Eugenia*, *Ficus* (fig), *Urtica* (nettle), *Euphorbia* (spurge), *Hedysarum*, *Panicum*, *Andropogon*, *Sida*, *Pandanus* (screw-pine), *Dracæna* (dragon-wood) *Conyza*, are very numerous in species, as are the same genera in India. In ferns, these islands are peculiarly rich. Again, their flora differs considerably from the South African; an analogy existing, however, in their possessing single representatives of the Cape genera *Erica*, *Ixia*, *Gladiolus*, *Bleria*, *Mesembryanthemum*, *Scripium*, and several arborescent *Synge-*

nesiæ. Still less is the affinity to the extra-tropical parts of New Holland. The similarity is stronger to the tropical portion of that country, of which the flora also approaches that of India. Single genera are all that it seems to possess in common with America; for instance, *Melicocca*, *Ruizia*, *Dodonæa*, *Dichondra*. The following are, perhaps, peculiar to this region, *Latania*, *Hubertia*, *Poupartia*, *Tristemma*, *Fissilia*, *Cordylina*, *Assonia*, *Fernalia*, *Lubinia*, and others. The flora of Madagascar seems very peculiar. It agrees with the islands last mentioned; and several genera are seen no where else than in them and Madagascar; for example, *Danais*, *Ambora*, *Dombeya*, *Dufourea*, *Didymomeles*, *Senacea*; several species also are common to both; as *Didymomeles Madagascariensis*, *Danais fragrans*, *Cinchona Afro-inda*. Still, among the 161 known genera from Madagascar, 54 only are found in the Isles of France and Bourbon; so that there might be good grounds for forming a separate region of the first; unless, perhaps, the east coast of Africa should come under the same. With New Holland and the Cape, Madagascar has probably still less in common than the two other islands.

1119. (18.) *Scitaminean region* (of the *Turmeric*, *Zedoary*, *Cardamom*, *Indian-shot*, &c.), or the Indian Flora. — To this appertain India, east and west of the Ganges, together with the islands between India and New Holland; perhaps, also, that division of New Holland which falls within the tropics. The *Scitamineæ* are here in far greater numbers than in America; also, though to a less degree, the *Leguminosæ*, *Cucurbitaceæ*, *Tiliaceæ*. The previously mentioned South American forms are rare, or else wanting. This region should be separated into several provinces; but as yet we know too little to undertake such a division with any degree of certainty.

1120. (19.) *The Indian highlands* ought to form one or perhaps two regions, their vegetation being very dissimilar to that of the lowlands: in the middle region, *Melastomæ*, *Orchideæ*, and *Filices*, appear to prevail; in the higher, the vegetation is more like the European and North Asiatic, and probably the Japanese: these districts perhaps constitute one region with the whole of Central Asia; but of all these countries we shall know much more when the Flora of India by Roxburgh and Wallich is completed.

1121. (20.) *The Flora of the South of China and of Cochinchina* partly resembles that of India, especially in regard to families; but still Loureiro's Flora contains a great many peculiar genera. It is true that perhaps the number of these genera might be reduced; but even then, the vegetation of this tract will probably prove sufficiently peculiar to constitute a distinct region.

1122. (21.) *The region of the Cassiæ and Mimosæ*, which prevail particularly in Arabia and Persia, seems likewise to have a good right to be separated from India, as it is already sufficiently distinct from the Mediterranean region (No. 3.); for, of 281 genera mentioned by Forskål, 109 only are found in the south of Europe. It is more probable that the Flora of Nubia and part of Central Africa appertain to this region. Abyssinia perhaps forms a distinct region, its elevated parts possessing such a different climate.

1123. (22.) *The islands in the South Sea* which lie within the tropics form perhaps a separate region; though with but a slender degree of peculiarity. Among 214 genera, 173 are found in India; most of the remainder are in common with America; for instance, *Chiococca*, *Weinmannia*, *Guajacum*. Of the species which exist equally in them and Asia, are *Zapania nodiflora*, *Kyllingia monocephala*, *Fimbristylis dichotoma*, *Tournefortia argentea*, *Plumbago zeylanica*, *Morinda umbellata*, *Sophora tomentosa*. In common with America, *Dodonæa viscosa*, *Sapindus saponaria* (soap-berry): with both, *Rhizophora Mangle* (mangrove tree): it has also some in common with New Holland, as *Daphne indica* (a species of *Spurge Laurel*). Peculiar families, or such as have there a decided maximum, can scarcely be cited; though, on the other hand, most of the species are peculiar. The *Bread-fruit* is among the characteristics of these islands; though this tree is not confined to the South Seas.

1124. *The limit of the present essay* does not allow of the intended introduction of the geographical situation of many of our more useful and important plants, which Professor Schouw has so ably delineated; such as that of the *Beech*, the *Vine*, the *Fir* tribes, the *Heaths*, *Corn*, and such fruits or vegetables as are employed as bread: the *Palms*, the *Proteaceæ*, which form so remarkably striking a feature in the Cape of Good Hope and in New Holland; the *Compositæ*, which are perhaps more universally diffused than any other kind of plant; the *Cruciferae*, to which the *Cabbage*, *Turnep*, *Mustard*, *Scurvy-grass*, &c. appertain; and the *leguminous* tribes, whose seeds (as the *Pea* and *Bean*) are so valuable for man, and whose foliage, as the *Lupine* and *Trefoil*, &c. affords most of the nourishment to cattle. We must endeavour to incorporate these with the vegetation of the various regions where they are found in the greatest abundance.

CHAP. II.

GEOGRAPHY CONSIDERED IN RELATION TO THE DISTRIBUTION OF MAN AND ANIMALS.

1125. *The geographic distribution of animated beings* is a branch of natural history which only of late years has engaged the attention of philosophers. The celebrated Blumenbach was the first, we believe, who generalised the numerous facts connected with the physiology of man, and proved that all the varieties may be referred to certain types of form, equally distinct in their physical structure and in their geographic distribution. Nearly at the same time, the geography of the vegetable kingdom engaged the attention of Baron Humboldt, the most accomplished traveller of the age; while, in our own country, the researches of Robert Brown have equally contributed to place Botanical Geography on a better footing than formerly. In this, as in other respects, Botany has taken precedence of Zoology; although it would be difficult to show why beings, so confessedly inferior in the scale of creation, should be deemed more worthy of attention than those belonging to the animal kingdom. Whether from this prejudice, or from the more varied and comprehensive sphere of zoology, which renders the subject too vast for the power of any one mind, certain it is that animal geography has been almost neglected. Isolated details, relative to particular countries, classes, or families, have been successfully investigated; but no one has yet attempted to generalise these materials, and use them towards the discovery of the laws of creation. It may be urged that the Fauna Suecica of the great Swedish naturalist is an exception; and that the writings of our acute and observing countryman White evince, on this subject, a patience and accuracy of observation hitherto unequalled: but without depreciating the merits of such works, we cannot consider them otherwise than as local lists, highly interesting indeed, so far as their limits extend, but totally distinct, in their object and nature, from such enquiries as regard the laws of geographic distribution. And here we may observe, it has of late become a fashion with certain writers to apply this term in much too general a sense. Any attempt to ascertain the range of particular species simply within a certain district or kingdom, is merely an enquiry into their *local* distribution; but if our views are extended beyond such confines, and we embrace a large portion of the globe, tracing the relations of its animals, with those of the remaining portions, it is then only that we enter upon the comprehensive subject of *geographic* distribution.

1126. *The enquiries relative to physical distribution, when directed to the animal world*, assume a higher importance than those, however interesting, which regard plants; for not only do animals appear incalculably more numerous than vegetables, but their natural range, dependent on a multiplicity of concurrent causes, appears to be much more distinctly marked. Plants, indeed, in a great degree, are stationary beings; but nature has wisely provided for their removal and dispersion to the most distant regions, by the diversified structure or tenacious vitality with which the seeds of numerous families are endowed; hence they become transported by various natural causes to distant shores, and, without any assistance from human aid, take root, flourish, and increase, in lands far distant from those which appear to have been their native regions. It is otherwise with animals: they may, it is true, be removed from their birth-place, and even become domesticated and naturalised elsewhere; but, with the exception of those which seem to have been originally destined for the service of man, such naturalisation is only effected by artificial means, and by slow degrees, through several generations. If such transported animals be left to themselves, or rather to the natural resources for supporting life peculiar to their new abode, they almost invariably pine and die. Again, plants, from being inferior to animals in the complexity of their structure, are, perhaps, necessarily dependent on fewer causes for retaining the vital energy; their dispersion is, consequently, upon the whole, much more extensive. It may be mentioned, in support of this remark, that out of 600 plants discovered in tropical Africa by Professor Smith, one twelfth have been ascertained, by Robert Brown, to be natives also of India and South America. Now, if either the vertebrated or invertebrated animals, not aquatic, of Western Africa, were compared in a similar way with those of the parallel latitudes in America and India, the proportion collectively would hardly amount to one in a hundred: indeed, with regard to the vertebrated orders, it is very questionable whether even one species is truly indigenous to tropical Africa and to America; so totally different are the zoological features of these continents, even at their nearest approximation: and yet, in the above number of plants, no less than twenty-two species are enumerated, as common to equinoctial Africa, India, and America. These facts, while they strengthen the belief that zoology is a more favourable field than botany for discovering the laws of natural distribution, lead us to consider the modes by which such enquiries are most beneficially prosecuted.

SECT. I. *Modes of investigating the Subject.*

1127. *The powerful effect produced on animals by temperature, food, and locality, are known to all: whether as regards the range of any particular species, or the numbers of which it may be composed. The effect of these agencies is indeed so great, that some writers have looked upon them as primary causes, and have imagined that by such laws alone has nature regulated the distribution of the whole animal creation. Very many instances, no doubt, from among the diversities of animal structure, may be urged in support of this theory; but how far it can be reconciled with other and more general facts, which will be apparent on a wider view of the subject, we shall hereafter investigate. It is clear that, by whatever laws Nature may have been guided, numerous exceptions will be found, proportionate to the vast and almost infinite variety she has displayed in her productions. There is, perhaps, no theory professing to explain the laws of Nature, whether on animal distribution or natural affinities, which the wit of man could possibly devise, that might not be supported with great plausibility, by certain facts, presented by those radiating threads of connection, and those apparent deviations from her general laws, which are everywhere apparent: yet these will frequently be opposed to other facts; and thus it becomes necessary, before determining on which side the preponderance of evidence lies, that we take as wide a survey of the general distribution of animals as the existing state of knowledge will admit. To set out with the belief that the laws of geographic distribution are fully ascertained, and that nothing remains but to make ourselves acquainted with the range of individual species, is a doctrine which can only be compared to those principles of classification insisted upon by the methodists of the last age in natural history, who considered all the generic groups had been discovered, and that future naturalists had nothing left but to appropriate to them the newly discovered species, in the best manner they could.*

1128. *Towards the discovery of the natural geography of animals there is, however, another mode of investigation, analogous to that we now pursue, in searching after the true series of their affinities: this is, to lay aside all preconceived theories, and to begin with considering the primary causes of geographic distribution to be, what in truth they really are, totally unknown. We are thus compelled to take a general survey of all the existing animals yet discovered, and now dispersed over the globe; and, from the facts so elicited, endeavour to attain such general inferences as are supported by a preponderance of evidence, furnished by nature herself. By the first method, as it has been truly said, we make nature bend to our own arbitrary theories; while by the second we humbly endeavour to receive her instructions; striving to obtain a glimpse of that stupendous plan which can never be fully understood by fallible and imperfect mortals.*

1129. *The geographic distribution of man is connected in our survey with that of animals; not so much in compliance with the popular notion, by which the noblest work of God is classed as a genus next to the brute, but because we may fairly presume, from the great diversity observed among the human species, that their variation and dispersion is regulated by some general plan; and that such plan may be analogous to that which is apparent in the distribution of animals. It may be urged, indeed, that such a remarkable coincidence, if proved, might tend to sanction the modern theory of classing man and brutes together; but the only legitimate construction which we think could be fairly drawn from such a fact would be, that there is but one plan of geographic distribution and of creation throughout nature.*

1130. *Against classing man with quadrupeds we must enter our decided protest. And here we cannot refrain from expressing regret that a naturalist of no ordinary talent has recently adopted this degrading theory, in apparent opposition to his former most just and philosophic views of the subject. He admits "the greatness of the gulf between man and the orang outang;" yet, because they possess certain analogies of physical structure, is it a necessary conclusion that they form one group? (*Linn. Trans.* xvi. 1. p. 22.) This, at least, was not the opinion (as this philosopher candidly admits) of either Aristotle or Ray, whom he justly considers the two greatest zoologists that have ever existed. It has been argued that the natural pride of philosophy withheld such men from classing themselves with brutes; but we are more disposed to think they were influenced by higher considerations. However this may be, there is an innate repugnance, or rather a disgust and abhorrence, in every human mind, enlightened or illiterate, against the admission of such a relationship. Revelation everywhere places MAN, even in his fallen state, in absolute contrast and contradiction with "the beasts that perish." It is not merely a feeling of pride; it is an innate loathing, engrafted in our nature, apparently for the very purpose of teaching us how immeasurably far we are removed from the brutes that have no understanding. Man has fallen, miserably fallen, but this is from the corruption of that pure spirit with which he was created: his form was then, as it is now; nor are we to suppose that *man*, as he came fashioned by his Creator, without sin, was clothed in a different form to that which he now, in a sinful state, exhibits. Are we then to place such a being in a zoological circle, surrounded with apes and baboons? or are material and immaterial natures so closely allied, that they may be classed together?*

1131. *There is another argument against including man in the zoological circle*, furnished by the very theory upon which that hypothesis is built. If the circular system is part of the system of nature, which at this time of day is perfectly demonstrable, every being has two affinities : by the one, it is connected to that which precedes it ; by the other, to that by which it is succeeded. Now, before we can bring man within the circle of the Quadrumana, on the strength of his affinity (whether near or remote) to the orang outang, we must show to what class of animals he is connected on the other hand. What then are our double affinities in the vertebrate circle? We may be allied distantly, perhaps, to *Simia*. But where is the second affinity? If this cannot be pointed out, the whole theory, in our estimation, falls to the ground, since the presumed *type* of the animal kingdom contradicts the laws by which creation is supposed to be regulated ; man exhibiting a single affinity, and the rest of organised matter a double one. Take him *from* the animal circle, — place him between matter and spirit ; — and his double affinities become at once apparent.

1132. *A general sketch of the physical peculiarities of man* in all his variations will first claim our attention ; the regions inhabited by the different races, and the affinities by which they appear connected, will also be briefly noticed. This part of our subject will be conducted on a somewhat different plan from that which we shall pursue in the sequel. The profound researches of Blumenbach and Cuvier, and the acute and patient investigations of Lawrence and Pritchard, have all conspired to produce nearly the same general conclusions on those points to which we shall particularly draw the reader's attention. These conclusions, moreover, demand our fullest confidence, from being founded on as rigid analysis as the nature of the subject will admit. Hence, we have no need, in this place, of entering into details, or of pursuing the same mode of investigation to which we shall have recourse when subsequently treating of animal distribution.

SECT. II. *Varieties of the Human Race.*

1133. *The varieties of the human race*, according to the opinion of the greatest comparative anatomist in existence, may all be included under three primary divisions, between which, in their typical examples, a very marked difference is observed. These M. Cuvier has termed, 1. the fair or Caucasian variety ; 2. the yellow or Mongolian ; 3. the black or Ethiopian.

1134. *The classification proposed by the celebrated Blumenbach*, although apparently different, is but a modification of that promulgated by Baron Cuvier. The former considers the Ethiopian type as divisible into three, 1. the American ; 2. the Negro ; and 3. the Malay. The latter indicates these additional races, but considers their peculiarities as less prominent than those of the two former ; he does not therefore admit them among the primary divisions of the human race. Without, at present, offering any opinion upon this question, we shall first take a rapid survey of the peculiarities, physical and moral, of all these groups.

1135. (1.) *The Caucasian race* (fig. 70.) is typically characterised by a white skin ; red

70

cheeks ; copious, soft, flowing hair, generally curled or waving ; ample beard ; small, oval, and straight face, with the features very distinct ; expanded forehead ; large and elevated cranium ; narrow nose ; and small mouth.

1136. *The moral feelings and intellectual powers of this race* have been developed in the highest degree of perfection which human nature has ever exhibited. The Caucasian has given birth to the most civilised nations, both in ancient and modern times, and has always exercised dominion over the rest of mankind, when not opposed by a vast superiority of physical strength. The mighty nations of antiquity, and the no less resistless powers concentrated in modern Europe, evince the superiority of this race in all that ennoble the immaterial part of man, and all that renders him formidable to his fellow creatures ; while every age witnesses a progressive but a surprising advance in all those qualities which indicate intellectual endowment.

1137. *The original seat of the Caucasian race* is supposed, as the name implies, to have been that lofty chain of mountains between the Black and Caspian Seas. This supposition, as Lawrence observes, is in unison with all that can be traced of the original abode of our

first parents ; and is further confirmed by the natives of these regions being, to this day, the most beautifully formed of all the inhabitants of the earth. From the Caucasian Alps different branches of this race diverge in every direction, as from a common centre ; the peculiarities of each being modified, altered, and finally lost, in proportion as they recede from the original seat of their tribe.

1138. *Of the branches of the Caucasian race*, the most powerful is the Pelasgic, which spreads over the greater part of Europe and Western Asia at its most northern limits, while it blends with the Mongolian race by means of the Fins and Laplanders. From this branch sprang the powerful nations of Greece and Rome, which have been succeeded by the mighty kingdoms of modern Europe. The next is the Syrian, which takes a southerly direction ; and includes that portion of Asia formerly inhabited by the Assyrians, Chaldeans, and the ancient Egyptians. The Indian branch, by some thought to be the same with the Pelasgic, passes to the East, and loses itself among the inferior castes of Hindostan. A fourth branch is the Scythian or Tartaric, which spread over the more northern parts of Asia ; and gave birth to those wandering and ruthless hordes who, by the physical power of numbers, devastated and finally overthrew the polished empires of Greece and Rome. The wandering and pastoral habits of this tribe have conspired to preserve their peculiarities unmixed with those of the neighbouring nations ; except, indeed, in Lesser Tartary, where this branch of the Caucasian race loses itself in the Mongolian.

1139. (2.) *The Mongolian variety* (fig. 71.) has these characteristics : — The skin, instead

71

of white or fair, is olive yellow ; the hair thin, coarse, and straight ; little or no beard ; broad, flattened face, with the features running together ; small and low forehead ; square-shaped cranium ; wide and small nose ; very oblique eyes ; and thick lips. Stature inferior to the Caucasian. In this race the moral and intellectual energies have been developed in an inferior degree. Tradition, indeed, has assigned to their most powerful nation, the Chinese, a high degree of civilisation, at a period when Europe was in a state of barbarism. Yet there are many circumstances which throw considerable suspicion on this fact : and even if it be allowed, a stronger proof could not possibly be produced to show the limited intellectual powers of this race ; for while the European Caucasian nations have advanced from rude savages to become masters of the world, the Chinese, after reaching a certain state of civilisation, have remained stationary, in every respect, through a long series of ages. Solitary exceptions cannot invalidate the fact ; and while we know that, not only in our own times, but so far back as history informs us, neither the sciences, the inventions, nor the improvements of the last three centuries have changed the Mongolian nations from what they then were, we can come to no other conclusion than that they are nationally incapacitated from further improvement. Cuvier supposes that the origin of the Mongolian race may have been in the mountains of Altaï. From thence it has spread over the whole of central and northern Asia, where it is lost among the Esquimaux on the one hand, and the Caucasian Tartars on the other. It further extends to the Eastern Ocean, and includes the Japanese, the Coreans, and a large proportion of the Siberians. Its limits to the south appears to extend no farther than to that part of Hindostan north of the Ganges, while the Mongolian features only predominate over those of the Indo-Caucasian in the lower castes of the Eastern Peninsula.

1140. *The origin of the Esquimaux and other polaric nations* found on the most northern limits of Europe and America, has given rise to great diversity of opinion. Arguments of nearly equal weight, but of opposite tendency, have been employed to show, on the one hand, that the Esquimaux belong to the American variety ; and on the other, to prove their structure more in unison with that of the Mongolian. The latter opinion has been supported by Mr. Lawrence ; and although we consider the weight of argument to be on this side, it appears not at all improbable that both these suppositions are in part correct. We have before observed, that the characters of each race become less and less apparent, the farther they are removed from their particular type. The proximity of the northern regions

of Asia to those of America, renders it highly probable either that their respective inhabitants mingled their races at a remote period, or that the northern Mongolians, whose civilisation is supposed to be of so great antiquity, were the first to emigrate, and people the northern regions of America. At all events, it appears certain that the Esquimaux nations unite in themselves many of the characters of two distinct races; and the only theory by which we can reconcile these doubts on their true origin, is that of supposing them to form the link of connection between the Mongolian and that race which spreads over the remaining portion of the new world. The brief notice we have now taken of the two most powerful races or varieties of the human form is sufficient to show their marked superiority over all others, whether as regards the symmetry or beauty of their physical structure, or the still more striking developement of their moral powers. Hence they both become typical, although in different degrees, of that perfection which the Creator has bestowed upon man, in this his probatory state of existence.

1141. *The third primary division* or leading variety of the human race, according to the views of the illustrious Cuvier, is the Negro or Ethiopian. This, again, presents three variations, considered by Cuvier as secondary, and by Blumenbach as primary. Although these variations are not so great as those between either the Caucasian, the Mongolian, or the African (the latter being considered the type of the Ethiopian variety), still they are sufficiently important to merit a particular specification under distinct names; and they are accordingly termed the American, the Ethiopian, and the Malay varieties.

1142. *In the American variety (fig. 72.)* the skin is dark, and more or less red; the hair black.

72

straight, and strong, with the beard small; face and skull very similar to the Mongolian, but the former not so flattened; eyes sunk; forehead low; the nose and other features being somewhat projecting. The moral and intellectual character of this race is in unison with the great difference it presents in outward form from the Caucasian. Like the Mongolian, it has remained stationary; but stopped at a point very much below that to which the Asiatics have reached. The ancient and now extinct empires of Mexico and the Incas may be considered analogous to those of China and India, exhibiting the highest point of civilisation to which the two races have ever reached; but farther than this the comparison cannot be carried. Arts, sciences, and all those intellectual endowments which have followed the progress of the Caucasian race, and to a certain extent belong also to the Asiatics, appear to have made little or no progress among the Americans, even in the gorgeous court of Montezuma. When that monarch despatched messengers to bring him an account of the first Spaniards who landed on his territories, so ignorant were the Mexicans of figures or of writing, that their report was made in complicated hieroglyphics, mixed with rude figures of the horses and persons of these unknown invaders. Their idolatrous worship enjoined no moral duties, like those of the superstition of Fo; and its rites were celebrated by human sacrifices of such a revolting nature as to be worthy only of demons. It deserves attention, that while the central portion of America presented in its original inhabitants such a degraded picture of the human mind, the northern nations of the new world, partaking more of the Mongolian aspect, evinced a higher degree of intellect. It is true they were only wandering tribes of hunters, yet they appear to have had a full belief in the existence of one "Great Spirit," and in a blissful immortality for themselves. The American race, blending with the Mongolian to the north, spreads over the whole of the new world; but whether any traces of this type exist beyond these limits, is a question which has not hitherto been investigated.

1143. *In the Ethiopian variety (fig. 73.)*, the skin is black; hair short, black, and woolly; skull compressed on the sides, and elongated towards the front; forehead low, narrow, and slanting; cheekbones very prominent; jaws projecting, so as to render the upper front teeth oblique; eyes prominent; nose broad and flat; lips (especially the upper one) particularly thick. The African or Ethiopian race has ever remained in a rude and comparatively barbarous state. Their cities are but congregations of huts; their laws, the despotic whim of the reigning

chief. Incessantly occupied in war or in the chase, they seek not to perpetuate their ideas. They have no written language, nor even a code of hieroglyphics. Abundantly supplied by nature with every necessary of life, they have retained their character unchanged, after centuries of intercourse with the most enlightened nations. Different branches of this type spread over the whole of the African continent, excepting those parts bordering the north and east of the Great Desert, which are occupied by the Caucasian Syrians, and where all traces of the negro formation disappear.

1144. *The Malay variety* (fig. 74.) varies in the colour of the skin from a light tawny to a deep brown, approaching to black; hair black, more or less curled, and abundant; head rather

narrow; bones of the face large and prominent; nose full and broad towards the tip. Under this variety, observes Mr. Lawrence, are included races of men very different in organisation and qualities. They nevertheless present certain general points of resemblance, which forbid their association with either of the foregoing varieties. Under this head are, therefore, included the inhabitants of Malacca, of Sumatra, and of the innumerable islands of the Indian Archipelago and the great Pacific Ocean. Most of these tribes are stated to speak the Malay language, which may be traced, in the various ramifications of this diversified race, from Madagascar to Easter Island. Their moral character is no less various than their outward form. In such as, by the colour of their skin and their woolly hair, show a general approximation to the African type, the mental powers are little developed. Their language, however, is stated to be peculiar, and they appear to have a copious bushy beard. (Lawrence, 489.) Branches of this division of the Malay race spread over the great islands of Sumatra, Borneo, and Andaman; and they appear also to occupy the Molucca and Philippine Islands. They are described as living in the same state of wild and savage barbarity as do the Bushmen of Southern Africa, and such other branches of the Ethiopian variety as appear the lowest in the scale of form and intellect. There is, however, a lighter-coloured and superior race, inhabiting some of the Indian islands, where an oval countenance, longer hair, and finer form, evince a much greater affinity with the Indo-Caucasian type on one side, and a strong analogy to the New Zealanders and Pacific tribes on the other. Proceeding along the same insular chain, we meet with "negro-like men" having curly hair, in the immense island of New Guinea, and in those south-western groups denominated New Ireland, New Hebrides, and New Caledonia. The natives of the vast continent of New Holland show strong indications of the same origin, and of the same untameable barbarism; yet their features are described as not unpleasant, their skin is rather copper-coloured than black, and their hair either curling or straight. The natives of the interior have been described as somewhat more civilised, and as speaking a language

different from that used on the coast. In the neighbouring island of New Zealand a considerable change from the black Malayan tribes takes place. The superior castes of these islanders in their persons are tall, active, and well made; their skin is brown, and their long black hair is sometimes straight, sometimes curling. A degree of intellect, superior to all the tribes we have enumerated, accompanies these personal advantages. Retaining many of the barbarous customs of their neighbours, the New Zealanders have, nevertheless, made some progress in the arts of life since their intercourse with Europeans: they believe in a Supreme Being, and in a happy immortality; and evince, in various ways, a desire to improve their condition. The natives of the Friendly Islands have the dark complexion of the New Zealanders, but are a much superior race. They are of the ordinary European stature, though some are above six feet high; their colour is a deep brown, verging in the better classes on a light olive; their features, like those of the New Zealanders, are various, approximating in some respects to them, and also to the true Europeans. Their progress in civilisation and in intellectual developement is considerable; as a proof of which, it is mentioned that they have terms to express numbers up to 100,000. The Otaheitians have long been celebrated for their personal beauty: the lower orders, indeed, are of the same brown tint so generally prevalent in the Friendly Islands, but in those of a superior caste this is gradually lost, until we find in the higher ranks a skin nearly white, or at least but slightly tinged with brown: and although the usual colour of their hair is black, yet it is of a fine texture, and frequent instances occur in which it is brown, flaxen, and even red. Their persons are well made, their features sometimes even beautiful, and a blush may be readily observed on the cheek of the women. The harmony of their language, and their simple though refined manners, have been universally remarked. These national characteristics extend to the Society Islands. *Lastly*, The natives of the Marquesas have been described as the finest race in the Southern Ocean: "in form they are, perhaps, the finest in the world." Their skin is naturally "very fair," and the colour of their hair exhibits all the varied shades (excepting red), which are found in the different tribes of the Caucasian race.

SECT. III. *On the Causes of these Varieties.*

1145. *The following questions naturally arise from considering these characteristics of the most prominent varieties of the human race; founded as they are on the concurrent testimony of travellers, and generalised by the most eminent physiologists: — 1. Whether these races, so dissimilar in their typical peculiarities, have originally proceeded from one, or from distinct stocks? 2. Are they so strongly marked as not to present many and great deviations? and, 3. To what causes are they to be attributed?*

1146. *In regard to the first origin of the human race, there have not been wanting those, who, disbelieving the evidences of the Mosaic history, have attempted to establish the hypothesis that these races have each sprung from different stocks; or, that they are, in fact, so many species. Now, this, at the best, is but an assumption perfectly gratuitous; not only because every record from which it could receive any support is expressly opposed to it, but because it is in direct violation of a primary and universal law of nature: a law by which the lowest being of the animal creation shrinks instinctively from intermixing its *species* with that of another. It has, moreover, been fully ascertained that, however great the variations of the human form may be, such variations among different breeds of the same species of animal are even greater. Unless, therefore, it can be proved that the laws of nature with respect to man and animals are contradictory, we shall, by attaching the least weight to the above theory, openly violate every principle of philosophic reasoning, as well as renounce all belief in revealed religion. On this head the Mosaic records are clear and explicit; and however the sceptic may deny their inspiration, he cannot bring forward, on his side, any testimony of such remote antiquity, or of such generally admitted credibility. As to the second question, it must not be understood that, in arranging the varieties of man under a certain number of divisions, and assigning to each a peculiar character, there does not occur many and very remarkable exceptions in each. So much, indeed, is this the case, that there are not wanting instances of native African tribes having the light skin of Europeans, Caucasians combining the Mongolian with the Malay structure, Americans resembling whites, and Africans with the copper-coloured skin of the American; nay, even in the same island or province, a great diversity both in language and in physical structure, is sometimes apparent, and this between tribes bordering close upon each other; so that, with the exception of a comparatively small portion of each principal race, we find so much diversity in the remaining or aberrant branches — the typical peculiarities become so modified, altered, or evanescent, that it is totally impossible to draw an absolute line of demarcation between them. This point has frequently been adverted to by a well-known physiologist, who says, "There is no circumstance, whether of corporeal structure or of mental endowment, which does not pass by imperceptible gradations into the opposite character, rendering all those distinctions merely relative, and reducing them to differences in degree. It is concluded, therefore, that every arrangement of these varieties must be in a great measure arbitrary." (*Lawrence's**

Lect. p. 472.) Yet, admitting this variation to the fullest extent, it cannot alter the correctness of the principle on which these distinctions are founded. Whatever might have been formerly thought as to the nature of terms employed by naturalists to designate particular groups of animals, it is now generally admitted that, throughout nature, there are no isolating distinctions, save such as separate species. The characters of every zoological group, of whatever magnitude or denomination, are subject to exceptions equally numerous. The typical peculiarities may, indeed, be prominent; but in proportion to the number of objects which are embraced under any definition, will be the diversity of those imperceptible gradations, those threads of connection, which shoot out in all directions, and unite not only genera and orders, but the primary kingdoms of the animal and the vegetable worlds. It is, therefore, irrelevant to argue that, because these divisions are liable to numerous exceptions, and are not always uniform and constant, they are either artificial or objectionable: for as we find that all natural groups, both in the animal and vegetable worlds, are subject to the same variations, they are therefore liable to the same objections. In short, if such reasoning is valid, the distinction between plants and animals can no longer be maintained; for it is to this day unsettled at what point the peculiarities of one are lost, and those of the other assumed.

1147. *The causes that may have led to these variations in the human species, form the only question of a general nature remaining to be discussed.* It has been argued by some writers, that particular climates, food, and modes of life, have gradually operated, through a succession of ages, to produce these effects on the colour, stature, and intellect of different nations. But, however greatly these causes may affect individuals, or even to a certain extent a whole people, they entirely fail when brought to solve our present question; were it otherwise, the same causes would naturally have the same effect on all the inhabitants of a particular region; but such, as is well known, is far from being the case. The negro, under a tropical sun, is black; while an Indian of Parà, in the same degree of latitude, is reddish brown. No race produces men more athletic, or more finely formed, than we ourselves have witnessed among the Gold Coast negroes; yet they inhabit, proverbially, some of the most pestilential districts of Africa. On the other hand, the New Hollanders, and the South African Bushmen, living in a salubrious climate, are described as lean, squalid, and with an appearance scarcely human. It is therefore obvious, that neither the physical nor the moral condition of man can be so affected by climate, or other external agencies, as to produce any great or permanent variation in his form. Indeed, when we consider that such agencies have not produced any physical change in any one nation, within the memory or the records of man, we are tempted to believe that, in a general point of view, their influence has been very slight: otherwise, there is no reason to doubt but that the same *natural* causes which operated at one period of time, would still continue to do so at another; and that we should find the descendants of Europeans long since settled in the New World, and in Southern Africa, beginning to assume the red tinge of the American, or the black skin of the Ethiopian. Still less can it be supposed that this departure from one common standard has been effected by civilisation, a consequent developement of the mental faculties, or even by diversified modes of life. Man, in remote ages, must have lived pretty nearly the same life in every region; whether as shepherds, hunters, or tillers of the field, their food, habits, and modes of life, must have been simple and regular. Whence comes it, then, that nations which still retain a great portion of what may be conceived their primitive simplicity, do not exhibit a corresponding resemblance in physical structure? If food, raiment, and moral improvement have such a powerful effect in modifying the human frame, it would naturally follow that tribes living nearly in a state of nature would all show a close approximation to one common type; that they would, in short, retain more of the lineaments and characters which must have belonged to our first parents, than if they had deviated from their primitive simplicity: yet the very reverse of this is the fact. The apparent aborigines of every nation are those in which the leading characters of their own tribe are most conspicuous; and which exhibit the strongest contrast to those of others. It is only when they have made some progress in the arts of life, when conquest or commerce has led to a union with other races, that the national characteristics, both personal and mental, give way, and begin either to blend or be lost in other modifications. These reasons, did they more immediately concern the purposes of this essay, might be much enlarged upon, more particularly as they have been offered by some deservedly eminent writers as a satisfactory solution of the question we are now discussing. Yet, allowing to all these causes the full effect they are known to have produced, we must yet confess they appear to us totally inadequate to explain the origin of the races of man. A writer intimately versed on this subject has well observed, that "external agencies, whether physical or moral, will not account for the bodily and mental differences which characterise the several tribes of mankind." (*Lawrence's Lectures*, p. 431.) We have, in short, now brought the enquiry to a point where human reason is baffled: there is neither history nor tradition to guide us in a research which carries us back to the obscurity of ages; to that remote period when the earth, for a second time, was again peopled, if not by a single pair, yet by the *three* sons of a single family.

1148. *We are now to view the question in another light.* It has been generally admitted, even by those who reject the Mosaic testimony, that the diversity in the human structure can in no way be accounted for by any known combination of *natural* causes : are we, therefore, to suppose, in a question which concerns the most perfect earthly being made by Omnipotence, that nothing *supernatural* is to enter ? that causes which effect the developement not only of the material but of the spiritual essence of man, have been left to chance ? Is it not more reasonable to conclude, that, for purposes unknown to us, a supernatural agency *was* employed ? and that the immediate descendants of the sons of Noah were as distinctly marked in their outward form as they were in their moral character ? The sacred writings, it is true, are silent on this particular point ; but it has been well observed that the Mosaic records were not written to answer philosophic enquiries. Those who, in the present age, have been the most profound investigators of nature, discover in every part of creation a symbolic relationship ; a mysterious system of types and symbols, which extends from the most complex to the most simple of organised beings : and when we know, for instance, that even the colours of a bird or an insect have a direct reference to such a system, and are employed as typical indications of its station in nature, can it be supposed that such a system does not extend to man ? That this will not, in the present infancy of our enquiries, admit of such direct and unanswerable proof as amounts to mathematical demonstration, we do not attempt to deny ; but that such a supposition is in harmony with that perfection which belongs to the works of Omnipotence, every reasonable person must admit. Nor are there wanting circumstances which give some degree of sanction to this belief. The curse pronounced upon Canaan as the son of Ham has unquestionably been fulfilled. Learned commentators agree in considering that central Africa was peopled by his descendants, and these have been for ages, and still continue to be, “a servant of servants,” to their more favoured brethren. Even their own despotic governments render the subjects but slaves. In them the human form is most debased, the divinity of mind least developed. They still exhibit those leading resemblances which rendered Cain a type of Canaan : with few exceptions, they are, to this day, but “wanderers and vagabonds” on the earth. The blessings pronounced on the two remaining sons of Noah, it has been well observed, are of a very different nature : Shem was more peculiarly favoured than his brother ; from his race not only the great patriarchs who typified Christ, but even Christ himself, descended. The peculiarity of the Jewish polity, which preserved the physical peculiarities of their race pure and unmixed through successive generations, leaves us in no doubt that they belong to the Caucasian type, in which, both in structure and intellect, a marked superiority over all the nations of the earth has been universally admitted. The early descendants of Japheth, as is plainly intimated by Moses, were eminently warlike. All writers agree in considering that from the Mongolian race descended those vast and overpowering hordes of barbaric warriors who at remote periods of time conquered all Asia, and devastated Europe under Attila, Zingis Khan, and Tamerlane. “It is remarkable,” says Dr. Scott, “that the first king of whom we read in authentic history, is Nimrod, the mighty hunter.” The same learned writer mentions that there is some ground for believing that the greatest part of Asia (now peopled by the Mongolian race) descended from Japheth. The population of Asia has been frequently mentioned as in an equal ratio to the superiority of its size over Europe, or rather, of those countries over which the Caucasian variety has spread. Thus, in every sense, it appears, that the promise to Noah’s first son, “God shall enlarge Japheth, and Canaan shall be his servant,” has literally and figuratively been fulfilled.

1149. *That the three sons of Noah overspread and peopled the whole earth,* is so expressly stated in Scripture, that, had we not to argue against those who unfortunately disbelieve such evidence, we might here stop : let us, however, enquire how far the truth of this declaration is substantiated by other considerations. Enough has been said to show that there is a curious, if not a remarkable, analogy between the predictions of Noah on the future descendants of his three sons, and the actual state of those races which are generally supposed to have sprung from them. It may here be again remarked, that although, to render the subject more clear, we have adopted the quinary arrangement of Blumenbach, yet that Cuvier and other learned physiologists are of opinion that the *primary* varieties of the human form are more properly but *three* ; namely, the Caucasian, the Mongolian, and the Ethiopian. This number corresponds with that of Noah’s sons : assigning, therefore, the Mongolian race to Japheth, and the Ethiopian to Ham, the Caucasian, the noblest race, will belong to Shem the *third* son of Noah, himself descended from Seth the *third* son of Adam. That the *primary* distinctions of the human varieties are but *three*, has been further maintained by the erudite Pritchard, who, while he rejects the nomenclature both of Blumenbach and Cuvier, as implying *absolute* divisions, arranges the leading varieties of the human skull under three sections, differing from those of Cuvier only by name. That the three sons of Noah, who were to “replenish the earth,” and on whose progeny very opposite destinies were pronounced, should give birth to different races, is what might reasonably be conjectured. But that the observations of those who *do*, and of those who do *not* believe the Mosaic history should tend to confirm its truth, by pointing out in what

respect these three races do actually differ both physically and morally, is, to say the least, a singular coincidence. It amounts, in short, to presumptive evidence that a mysterious but a very beautiful analogy pervades throughout; and teaches us to look beyond natural causes, in attempting to account for effects apparently interwoven in the plans of Omnipotence.

1150. *To reconcile the different theories regarding the number of primary variations in the human form is our next object.* The greatest authorities on this subject are Blumenbach and Lawrence, Cuvier and Pritchard. The first two, as already observed, maintain that the primary divisions are five; while the latter, with more show of reason, contend that there are but three, although they readily admit the distinctions assigned to the other two. In what manner, therefore, can these opposite theories be reconciled? To do this, we must revert to a third and a very remarkable one, which, although it has hitherto been solely detected to the animal kingdom, will yet be found to exercise a very important influence on the present question: we allude to the circular theory of MacLeay. It is the opinion of this learned naturalist that every group of organised beings divides itself, as it were, into two branches of affinities, which, finally uniting again at their opposite extremities, form a circle; and that this disposition of affinities holds good, not only in every group, of whatever magnitude or denomination, but throughout the animal and the vegetable world. It has been further shown that as such a circular arrangement of beings cannot, of necessity, present any absolute or isolated divisions, (for it could not then be continuous and circular), yet, that there may be traced, in each circle, five deviations or varieties of structure; which, however conspicuous in their typical examples, are blended and lost the nearer they approximate to each other. Now, so far as regards the affinities of animals, this circular theory has been demonstrated; but it long remained a matter of doubt what number of *primary* divisions every group contained. Mr. MacLeay considers there are five; and this accords with Blumenbach's arrangement of the human species. M. Cuvier, and Dr. Pritchard, as we have before stated, limit the leading varieties of man to three. In our arrangement of the order Insectores (*North. Zoology*, vol. ii.), one of the most comprehensive divisions in ornithology, we have shown that the primary divisions of every natural group are only *three*; one of which, by forming a circle of its own, includeth *three* of those pointed out by Mr. MacLeay, — thus making the number *five*. Now, this theory, on the natural divisions of birds, rests upon no speculative assumption; it is founded on the most rigorous and minute analysis, and has thus been capable of mathematic demonstration. The question, whether this theory is applicable to one part only of the animal creation, or whether there is presumptive evidence to conclude that it pervades all nature, has been discussed at some length in the "Introductory Observations on the Natural System," prefixed to the same work. In some respects the *ternary* and the *quinary* theory of divisions may be thought virtually the same; and so far as regards our present subject, considered abstractly, this observation may be true. We can analyze a group of insects, of birds, or of other animals, but how are we to analyze the different modifications of man? The thing is utterly impossible. Now, as every true theory must rest upon analysis, our present views on this subject would be purely speculative, did they not so strikingly and wonderfully coincide with those in other departments of nature, into which we can prosecute minute research, and attain logical demonstration. Besides, by supposing that there are *five* principal variations in man, each equally important with the other, we entirely destroy the beautiful analogy between these variations and the sacred writings. But without entering farther upon this question, it will be sufficient for our present purpose to repeat, that, in regard to man, the views of Blumenbach and Cuvier are virtually the same; for if, with the former, we reckon five, there will be two groups more conspicuously typical of perfection, and three others, which, however distinct in many respects, possess several characters in common. If, on the other hand, we follow Cuvier and Pritchard, and restrict the number to three, we have the Caucasian and the Mongolian as the two principal groups, while there is a third, typically represented indeed by the Ethiopian, but still so diversified as to admit of a threefold division, into the American, the African, and the Malay varieties.

1151. *That the variation of man has been regulated by similar laws to those which have been traced throughout nature, is a conclusion supported by strong and presumptive evidence; drawn both from the sacred writings, and from inferences in zoological science, which no one has ventured to dispute.* In establishing this point, I have studiously confined myself to such facts, connected with the physical history of man, as rest on high and indisputable authority. On a subject so vast and intricate, illustrated by the united labours of the most acute philosophers now living, little that is new could have been said, and that little might have been suspected of being brought forward to favour a particular theory. In the preceding sketch of the principal differences in man, we have, therefore, merely condensed the observations and facts detailed in the writings of Blumenbach, Cuvier, Pritchard, Lawrence, and Sumner; rather wishing, that, whatever inferences are drawn from such sources, the facts themselves should rest on testimonies of so much weight.

1152. *The order in which these races are here placed* leads us to other considerations. Blumenbach is of opinion that the American form is intermediate between the Caucasian and Mongolian; but we have failed to discover any assigned reason for such a disposition, which also seems at variance with the progression of developement. The geographical situation of the two continents, as we have before observed, renders it highly probable that the American variety is more immediately connected with the Mongolian; and the simple fact, that the Esquimaux have been by some considered as of Asiatic origin, while by others they are thought to exhibit more of the American type, is, perhaps, the strongest proof of their intimate relationship to both. Neither does the American race exhibit any direct affinity to the Caucasian; while, on the contrary, both their physical structure and mental developement seem to place them in close approximation to the Africans. For these and subsequent reasons, we have felt no hesitation in adopting the series intimated in the *Règne Animal*. We must now advert to another peculiarity in this arrangement, which renders its similitude to the zoological series still more remarkable. This is the progressive series of affinities, resulting from placing the five leading varieties in the order in which they have been here noticed. The Caucasian and the Mongolian races present the highest degree of civilisation, although in very different degrees when compared with each other: the regions they respectively inhabit, in like manner, approximate so closely as not to be divided by water. Yet the configuration of these races is so remarkable, that they cannot be mistaken or confounded. In the third race, comprehending the American, the Malay, and the Ethiopian, very marked deviations from the typical endowments of the two former are manifest. This inferiority is first shown in the American, whose outward form and moral capacity is nevertheless superior to the African. Yet, as nature in the animal kingdom is ever prone to retrace her steps, and to return again to her original type; so we observe that, after exhibiting, in some of the African hordes, the lowest debasement of the human form, and the least capacity for mental improvement, she begins, as Blumenbach observes, in the diversified races of the Malay variety, to show a progressive but a very marked inclination to return through them to the Caucasian type. So strong, indeed, does this appear in many tribes of the South Sea Islanders, not only in the beauty of their forms, but in the advance they are continually making towards intellectual improvement, that every voyager, who has visited their shores, concurs in likening them to Europeans.

1153. *The inferences to be drawn from this circular disposition* are important, if merely considered in relation to those systems, which, by presupposing a lineal scale in creation, would place the negro in immediate contact with the monkey. Now, without laying any stress upon that primary characteristic of man, a reasoning, thinking, and immaterial soul, of which the body is but a temporary receptacle, we must, before we consent to this hypothesis, get over difficulties which appear insurmountable. That the Ethiopian holds the lowest station among the varieties of his species, is fully granted; but that this admission implies an affinity to the ape, does by no means follow. There may be an approximation: but it is necessary, before we decide on the *degree* of such approximation, that we should examine the relative affinity which the Ethiopian bears to the Caucasian. For if it should appear that the difference between the most perfect and the most imperfect of the human races is unquestionably less than between the latter and the brutes; or, in other words, that the similarities between the negro and the Caucasian are decidedly greater than those between the negro and the ape; we must admit that this latter approximation is too slight to be termed an affinity. If, on the other hand, we consider man only as a material being, he stands so far removed from brutes — the interval between him and them is so great — that it would be a violation of natural affinities, and certainly an insult on his better nature, to class him in the same system. To arrive at a just conclusion on this subject, we must not look so much to any *one* point of comparison, or to mere anatomical analogies, but bring the distinguishing characters of each into direct comparison. Does the negro, it may then be asked, evince a deficiency of those qualities which belong to the Caucasian? we allude not to the natural affections, for these are, in some degree, common to brutes; but in self privation, compassion, and heroic love of their country. Are they incapable of learning European arts, or of inventing others suitable to their wants or habits? To deny them such qualities would be preposterous: they possess the germs of others infinitely higher, which, under favourable circumstances, have produced expert artisans, skilful physicians, pious divines, and pleasing poets. "I protest especially," observes Mr. Lawrence, "against the opinion which either denies to the Africans the enjoyment of reason, or ascribes to the whole race propensities which would degrade them even below the level of the brute. It can be proved most clearly, that there is no circumstance of bodily structure so peculiar to the negro, as not to be found also in other far distant nations; no character which does not run into those of other races, by as insensible gradations as those which connect together all the varieties of mankind." (p. 428.) To pursue this comparison farther is needless; and to ask whether the least indication of such powers have ever been manifested by the quadrumanous animals would be ridiculous. The learned and eloquent Bishop Sumner forcibly observes, "There

is nothing philosophical in the comparison of a being possessed of improvable reason, with one that is governed by natural instinct, because there is no just affinity between the talents which are compared." (*Records of Creation*, vol. i. p. 23.) We consider this argument as conclusive. To class man, therefore, in the same zoological division with apes, merely because both have a hyoid bone, is, to our apprehension, as glaring a violation of natural affinities as to arrange bats with birds, because both fly in the air, and possess a crest to their sternum. So far, indeed, from considering man as the type of a zoological order of brutes, we cannot allow that he even belongs to the same system in which they are arranged. It may be, that the deviations of his structure are regulated by those laws which govern the universe; yet, nevertheless, by his nobler qualities (which in fact are his true distinctions) he belongs to a higher order of beings: that he is, in short, a link between matter and spirit; that he carries this evidence, through revelation, within himself; and will hereafter be most assuredly rewarded or punished, according as he suffers his spiritual or his earthly nature to preponderate.

SECT. IV. *On the Geographic Distribution of Animals.*

1154. *The geographic distribution of animals* over the globe, is the next subject of enquiry. In the general outline of the variations in man which has been given above, we have deemed it more important to seek after general results than to enter upon minute details. Our attention has been fixed, not so much on those ramifications which shoot out near the extremities of every branch, and become too indistinct for clear elucidation, but rather to the leading branches themselves, on the nature of which there has been little diversity of opinion.

1155. *In the enquiry regarding the geographic distribution of animals*, on which we now enter, the same mode will be adopted, but with this difference, that whereas we have hitherto drawn our inferences solely from the facts and general opinions of others, we shall now put aside all theories heretofore promulgated on the distribution of animals, and merely depend on simple facts for the support of those inferences which they may appear to sanction. We shall first briefly notice those principles which have been applied to elucidate the phenomena of animal distribution, and then enquire how far they appear conducive to that end.

1156. *That climate, temperature, soil, and food*, exercise a paramount influence on the distribution of animals, has been generally believed; and on this assumption naturalists have divided the world into climates, zones, or provinces regulated by degrees of longitude or latitude. Such has been the favourite theory not only of physiologists, but of professed naturalists, whose knowledge of details might have furnished them with insuperable objections against such views. Thus, the celebrated entomologist Fabricius conceived that the insect world could be naturally divided into eight climates: one of which is made to comprehend all those mountains, in every part of the world, whose summits are covered by eternal snow. It is, therefore, not surprising that M. Latreille should consider such a theory as altogether vague in some respects, and arbitrary in others. But will not the latter objection be equally applicable to the distribution which this eminent naturalist has himself proposed for this part of the creation? At least, such is the opinion of one fully competent to judge the question. "A chart of animal geography," says Mr. Kirby, "which is divided into climates of 24° of longitude and 12° of latitude, wears upon its face the stamp of an artificial and arbitrary system, rather than of one according with nature." On much the same principles another theory has been built, by which the earth is divided into seven zoological provinces, or zones, mainly dependent on the respective degrees of latitude they occupy. Now, so far as regards one of these provinces—that comprehended within the arctic circle—this view of the subject, at first sight, appears perfectly just: for there is not only a strong analogy between the groups of animals inhabiting such parts of the two continents as enter into this circle, but there is also an absolute affinity between them; inasmuch as the arctic regions contain not only genera, but numerous species, common to both continents. This theory, however, loses all its force when applied to such divisions as are made to include the tropical regions of Africa, America, and Asia, in one province, and the southern extremities of America and Africa in another. The zoologist immediately perceives that the only relation which these countries bear to each other in their animal productions, is purely analogical; and we are thus compelled to relinquish a theory which appears correct only in one point of view. These and other less eminent writers appear to have erred in the very foundation of their methods. They assume as granted, what has never yet been proved, that temperature exercises a primary influence on animal distribution. Were such the case, it would naturally follow that the animals of such parts of America, Africa, and Asia, as are placed in corresponding degrees of latitude, would be nearly of similar species; or, at least, of the same natural genera. Yet such, as we shall hereafter show, is not the fact. Between the animals of these regions there is, indeed, in very many instances, a strong analogy: such, for instance, as is apparent between the *Trochilidæ* of the New World, the *Cinnyridæ* of Asia and Africa, and the *Melliphagidæ* of the Australian islands. Such, again, is that between the Toucans of America (*fig. 75. a*), and the Hornbills of Asia

(fig. 75. b). Yet not one species of these birds occur in any two of these countries. Nevertheless it cannot be denied, that the temperature and configuration of a country exercises a powerful influence on the distribution of animals. But these effects are of a secondary nature, and totally fail when employed to elucidate those general principles which appear to regulate the whole system of animal geography. Such agencies, however, may be safely allowed to possess much weight, when we descend to details, and investigate the local Fauna of any particular country or district. It has been observed by the celebrated Humboldt, and confirmed by an authority of nearly equal weight, that, with regard to certain tribes of insects, their geographical distribution does

not appear to depend solely on the degree of heat or humidity to which they are exposed, or on the particular situation they inhabit; "but rather on local circumstances, that are difficult to characterise." This opinion is in unison with the whole tenor of the facts to which we shall hereafter advert. We must, therefore, agree with Mr. Kirby, and consider that the distribution, not only of insects, but of animals in general, is "fixed by the will of the Creator, rather than certainly regulated by any isothermal lines." (*Introduction to Entomology*, vol. iv. p. 484.)

1157. *The distribution of animals, in connection with that of the human race, remains to be considered.* From what has been already stated, there appears strong reason to believe, that the variations in the structure of man and of animals are regulated by similar laws; and this supposition will receive considerable weight, should it appear, upon investigation, that those divisions of our globe which have been apportioned to the different varieties of man, are equally characterised by certain peculiarities in their animal tribes. Now, to establish the truth of such a theory, it is necessary to wave all general abstract reasoning, and to draw deductions from known facts. And it is equally obvious that, if such facts are to be collected from the whole animal kingdom, this essay must be extended to several volumes, even admitting that our materials were sufficiently extensive for such a purpose. But the truth is, that the data for such a comprehensive investigation are so few, so meagre, and so unsatisfactory when compared with the diversity and vastness of the subject, that they sink into insignificance. Nor will this appear surprising, if we consider the astonishing number of animals that have been already described by naturalists, or are known to exist in cabinets; setting aside the hosts of species yet unknown, which, in many departments, may possibly amount to double or treble the number we are acquainted with. Yet, as details of some sort must be gone into, it becomes absolutely necessary to select for such a purpose some one department of nature; and the results which might follow, we may fairly presume, would be in unison with those that would attend the investigation of other divisions of the animal world, could they be investigated upon the same principles. Nature, in all her operations, is uniform: and it cannot be supposed that the distribution of quadrupeds, birds, insects, or reptiles, would each be regulated by different laws.

1158. *In choosing, therefore, from the animal kingdom some one order of beings for particular investigation, it might be thought that the distribution of quadrupeds would present the best field of enquiry.* It possibly might, did not their investigation involve certain points of controversy connected with geology, which, however important, are not so intimately connected with our present object as to render their discussion necessary in this place. The division of reptiles is subject to the same objection, and is not sufficiently extensive for our purpose. The annulose animals, on the other hand, are so numerous that they appear to baffle our enquiries; nor can we hope, while yet in the infancy of geographic natural history, to do more than has been already done by the genius of Latreille. Birds alone remain. It has, indeed, been argued, that no very certain results can attend the study of their distribution; because, from possessing the powers of locomotion, and the instinct of migration, in a high degree, they appear more widely dispersed than any other class of animals. How far this may be true has never, indeed, been made apparent; yet, allowing the assertion its full weight, we may safely conclude, that if, under these disadvantages, any definite notions of geographic distribution can be gathered from the study of such volatile beings, the results would be materially strengthened if found to harmonise with what is already known on the distribution of other orders of animals, which, from their physical construction, are less capable of extending their geographic range. It is here, however, necessary to premise, that in this, as in all other branches of natural history, the accounts and relations of travellers, not in themselves zoologists, must be received with great caution. Unacquainted with those nice distinctions upon which not only the differences of species, but of genera and families, are now known to depend, they perpetually contradict, by a hasty application of well-known names, some of the most acknowledged truths in animal geography. Nor can the facts detailed in the compilations of more scientific writers be always depended upon. The voluminous works of a most industrious and zealous ornithologist of the Linnæan school

abound with mistakes of this nature; wherein not only species but genera are said to inhabit countries where they have never been found except in the vague and erroneous narratives of travellers. It is the misfortune of those who complain against the multiplicity, and regret the adoption, of modern divisions, that by so doing they debar themselves from studying the variations of physical structure, and neglect the main clew to enlarged conceptions of zoological science. It is necessary to make these allusions, that the reader may be apprised of our adoption, in this place, of the principal modern genera; and our rejection of many of the localities erroneously given to certain species in the general histories of birds.

1. *The Caucasian or European Province.*

1159. *The ornithological features of the Caucasian range*, or of the regions over which the Caucasian variety of the human species is said to be distributed, will first claim our attention. It has been already shown that this range comprises such portion of Africa as lies north of the Great Desert, nearly the whole of Europe, and a considerable extent of Western Asia. The ornithology of the countries bordering upon this region has been but partially investigated; yet sufficient is known to show that it presents a mixture of those species which have their chief metropolis in other countries. It has been thought that the animals of the arctic circle are so peculiar, as to justify us in considering that region in the light of a distinct zoological province. The objections against this idea have already been alluded to; and they become more forcible when we discover, that on calculating the number of birds, both terrestrial and aquatic, which occur within the arctic circle, they do not amount to more than twenty-two; and that most of these, during the greatest portion of the year, are found in the more northern parts of Britain and America. They probably occur in similar latitudes on the Asiatic continent; but on this point our information is defective.

1160. *The swimming birds* are known to possess a very wide range; but this is less extensive, perhaps, than is generally imagined. The number of species found on the shores of Europe and Northern Africa, independently of those more peculiar to the arctic circle, is sixty. Of these, two alone have been discovered in the four quarters of the globe; three are common to Europe, Asia, and America; one to Europe, Asia, and Southern Africa; and twenty-seven to Europe and Northern America: thus leaving twenty-seven (or nearly one half the number of European natatorial species) as peculiar to this zoological division of the world.

1161. *Among the Grallatores, or waders*, some particular species are so widely dispersed as to suggest the idea that the geographic range of this order is even wider than that of the *Natatores*; and this, generally speaking, may be true. Of the sixty-five species described as natives of Europe, thirteen only occur in America, and two only can be reckoned arctic birds, although several others occasionally frequent those regions. Of the remainder, four

occur in Asia; two in Asia and Africa; four in Asia and America; seven in Asia, Africa, and America; and the Whimbrel (*fig. 76.*) (*Numenius Phæopus*) is said to be the same in all the five divisions of the globe. It is consequently among the wading birds that we find those whose range is most extensive; yet, on a general calculation, the number of species peculiar to Europe is considerably greater than those of the *Natatores*; the former being as one to two, the latter nearly as one to four. It thus appears, that, even among birds of the most vagrant habits, the ornithology of Europe is characterised by a decided superiority in the number of its own peculiar species.

1162. *The rapacious birds, next to the aquatic orders*, are thought to be the most widely distributed; particularly the nocturnal species. It is very remarkable, that out of thirteen different owls inhabiting Europe, five only are peculiar to this continent; and two of these more particularly frequent the arctic regions. Of the rest, five occur in America, two in Southern Africa, and one both in Asia and America. The *Falconidæ*, or diurnal birds of prey, in regard to their species, have a more restricted distribution; yet, of these, the eagles enjoy no inconsiderable range. Out of eight discovered in Europe, one is more properly arctic, three have been found in several parts of Africa, and one occurs in America; leaving three only to Europe. It is singular that those rapacious birds which, from the peculiar structure of their wings, have been supposed to enjoy the greatest powers of flight among their congeners, are those most restricted in their geographic limits. This is proved by the fact, that out of eight genuine falcons occurring in Europe and Northern Africa, two only have been discovered in America. It has, however, recently been stated that the *Falco peregrinus* of Australia is identically the same as that of Europe: neither does Southern Africa, we believe, possess a single European species, or not one of those inhabiting the northern extremity of that peninsula; the *Montagnard* of Le Vaillant, long confounded with the European Kestrel, being a decidedly distinct species. Upon the whole, the

distribution of the forty-four species of European *Raptores* will stand thus: three are Arctic, eleven are found also in America, two in Asia and Africa, and one in Asia and America; leaving twenty-seven, or more than one half, peculiar to European ornithology.

77

THE GREAT BUSTARD.

Asia. We consider very few of the European Gallinaceous birds as truly arctic; for nearly all the species appear to occur as plentifully beyond those regions as within them. Many of the meridional European birds, as *Upupa Epops*, *Oriolus galbula*, *Coracias garrulus*, &c., might with equal justice be classed as peculiarly characteristic of Central or Southern Africa. It nevertheless appears that, even among the Gallinaceæ, fourteen out of twenty-seven have their principal seat in Europe. The remainder are thus apportioned: five extend to Western Asia, five to the confines of the great African desert, two are dispersed in Central Asia and Africa, while two only occur in North America.

1164. The *Fissirostral* birds, typically represented by the swallow, are, of all the insectivorous tribes, most conspicuous for their powers of flight. With but one exception, the

78

EUROPEAN KINGFISHER.

European Kingfisher (*Alcedo europæa*, fig. 78.), they are all migratory: hence we find that most of the species occur beyond the limits of the European Fauna. The proportion of those which appear confined to Europe and Northern Africa is as one to three.

1165. The small *Granivorous* birds not only present a great diversity in their species, but a considerable preponderance in their numerical amount. Forty-one are included in the European list; two of which, at certain seasons, frequent the polar regions in great numbers, but are nevertheless abundant in all the northern latitudes; seven inhabit North America, and three extend both to Asia and Africa; so that Europe may be considered the metropolis of nearly thirty peculiar species.

1166. The *Scansorial* birds are few; yet eight out of the fifteen recorded as European are unknown in other regions. It is among the *Insectivorous* and soft-billed birds that we must look for the principal ornithological features of any particular region. The immense family of Humming-birds in the New World, and of Melliphagidæ, or Honey-suckers, in the Australian islands, would alone be sufficient to mark these regions with a distinct zoological character. To what cause we are to attribute the fact that these birds, by no means deficient in the power of flight (which, indeed, in many of them is considerably developed), should nevertheless be so strictly confined within certain geographic limits, remains unexplained. We can only in this place illustrate the fact. Of eighty-five species belonging to the Linnæan genera of *Turdus*, *Sylvia*, *Parus*, and *Muscicapa*, eighty-two are strictly European. In this number we of course include those which migrate, at certain seasons, to Northern Africa and Western Asia; for these regions, it must be always remembered, come within the zoological province we are now treating of: yet, if we deduct the number of those which have actually been detected in parts beyond the shores of the Mediterranean on one side, and Western Asia on the other, they will amount only to ten; leaving seventy-two as a marked peculiarity in the ornithology of Europe. In further proof of the limited range of these families, it may be remarked, that three only out of eighty-five have been detected in America; and that the identity of one of these (*Parus atricapillus* L.) with an European species (*Parus palustris* L.) is very questionable.

1167. The *Omnivorous* birds, as the *Sturnidæ*, *Corvidæ*, &c., are the last requiring notice. A few of these appear widely dispersed; but upon the whole, several species, and even peculiar genera, are left to characterise this portion of the world. We may state their number at

twenty-one: thirteen of which, or more than one half, habitually reside in Europe; four occur in Northern and Central Africa; one (*Pastor roseus* T.) inhabits both the table land of Asia and the deserts of Central Africa; and three have been found in America.

1168. *These details*, tedious perhaps to the general reader, but interesting to the man of science, it becomes necessary to dwell upon, before any valid deductions can be drawn from the facts they exhibit. In this difficult and somewhat laborious investigation we have been much assisted by the writings of Wilson, Temminck, and Le Vaillant; but more than all by the liberality which throws the magnificent collections of the French Museum open to the use of all scientific enquirers, whatever their object or their nation may be.* It cannot, however, be supposed that, even with greater sources of information, some inaccuracies may not have occurred. Such calculations, in short, from their very nature, can never be perfect; because they are founded upon present knowledge, and *that* is perpetually extending. The most that can be done is to make as near an approximation to the truth as circumstances will admit; and having done this, the result may be entitled to some degree of confidence.

1169. *As a general recapitulation of the European birds*, we may state the total number, exclusive of a few which occasionally appear at remote intervals as stragglers, at 388. Of these, thirty-one are more peculiar to the arctic regions of Europe, America, and probably of Asia; the proportion being as one to thirteen. Sixty-eight (forty being aquatic) occur also in temperate America; nine are dispersed over four divisions of the globe, to neither of which can they be particularly appropriated; and either one (*Numenius Phæopus*) or two extend to Australia. With these deductions, the number will thus be reduced to about 280. If from these we abstract such others as may *possibly* have a partial range beyond the limits already defined, the number may be further reduced to about 250; so that, even with this allowance, nearly two thirds of the birds of Europe, Northern Africa, and Western Asia may safely be considered as zoologically characteristic of those countries.

1170. *Another character in European ornithology* deserves attention. This regards the superior number of generic types which it exhibits, in proportion to the number of species. These genera amount to 108, omitting those which have not been generally adopted, or which, from the modifications of form being but slight, should more properly be termed sections. The proportion which these genera bear to the number of species (estimated before at 388) amounts to more than two to seven; or, in other words, does not give seven birds to two genera. It is further remarkable, that most of these exhibit in their structure the *greatest perfection* of those orders or families to which they respectively belong; and which groups are denominated by naturalists *typical*. True it is that such genera are widely dispersed; but in no division of the world do they appear so numerous, in proportion to the species, as in Europe. This remark not only applies to the typical genera, but is frequently applicable to the number of species they respectively contain. One instance may suffice. The noble falcons, or those to whom the generic name of *Falco* is now restricted, are generally considered the most typical group of their family: of these, the Kestrel (*fig.* 79.) and five others have their metropolis in Europe and Northern Africa. The whole of

THE KESTREL.

North America has hitherto produced but four. Le Vaillant enumerates the same number from Southern and Central Africa. Those of Central Asia are not known; but only two have been recently described as peculiar to the vast regions of Australia. Now, if we merely look at these respective numbers, the difference does not appear very remarkable; but when the great inferiority between the Caucasian regions and those of America, Africa, and Australia, *in point of extent*, is taken into the account, it will be immediately seen that the proportion of these eminently typical species in the European regions is particularly great. Among the typical groups of the wading and swimming birds this is still more apparent; so that, if we endeavour to define what is the most striking feature in the ornithology of this zoological province, none is so remarkable as the number of purely typical groups. This peculiarity will be more apparent on looking further into the matter. The total number of birds throughout the world, existing in museums or clearly described in authentic works, may be estimated at 6000. These have been arranged under about 380 genera; but as several of these genera will comprise more than one sub-genus, we will put down 400 as a nearer approximation to correctness: this would leave rather more than fourteen species to each generic group; while, if the ornithology of Europe and Northern Africa is alone considered, the proportion is no more than one to three; and even this will be further diminished when those geographic groups among the *Fringillidæ* and *Sylviadæ*, which are decidedly peculiar to this portion of the globe, are investigated and defined. Now, it is very

* We have been *officially* informed that, by the laws of the Zoological Society of London, no one can receive permission to make use of their Museum, for general scientific purposes, who is not a member.

singular that, in speaking of the leading varieties of the Caucasian race, a writer, whose testimony is no mean authority, observes, "that the tribes among the Caucasians are more numerous than in any other." And again — "Whether we consider the *several nations* or the individuals in each, bodily differences are much more numerous in the highly civilised Caucasian variety than in either of the other divisions of mankind." (*Lawrence*, p. 442. 475.) When we glance over the list of those nations generally supposed to have sprung from this type, we are struck with the justice of these observations. It is the more remarkable, as the regions they occupy are disproportionably small, when compared with those peopled by the Mongolian and Ethiopian races. That there are instances wherein typical forms of higher groups than genera do not occur within the European range, is a circumstance which will not materially affect the question. Thus the only bird we possess belonging to the *Tenuirostres* of M. Cuvier is the European Hoopoe (*Upupa Epops*), which is certainly not a typical example; but this, so far as tribes are concerned, is the only exception to the rule. It is curious, also, that this exception should occur in that division which comprises the smallest and weakest of birds. If we descend to families, there is scarcely one *pre-eminently typical* of its own perfection which is not European. A further objection may possibly be urged, that, although such forms are indeed abundant in this Fauna, they are nevertheless found in nearly every other part of the world; and cannot, therefore, be looked upon as characterising Europe more than any other country: but this will not be a just conclusion, unless it is first shown that the proportion of such types to the total number of European species is not decidedly greater than in any other region. Now the facts we have already stated prove this beyond doubt.

1171. *These results*, obtained from unquestionable data, are so important to our present enquiry, that their hasty notice would not have been sufficient. The materials for illustrating the ornithology of Europe are naturally more numerous than can be expected for other portions of the globe; and it became very desirable to ascertain how far the ornithology of those regions, occupied by the Caucasian race, presented a peculiarity of character sufficiently strong to show a mutual relationship with the geographic distribution of this variety of man. We are, I think, sufficiently authorised to consider that both are in unison. At least, there are so many singular points of analogy, as to render it highly probable that there exists an intimate relationship between the distribution of one race of mankind and one of the principal geographic divisions of birds.

1172. *How far this view of European ornithology* would be borne out by an extended investigation of other orders of animals, it is impossible to say. Yet even if our present limits would permit the enquiry, we should have to rely more upon theory than facts. Many of the quadrupeds of Europe have long been slowly but certainly disappearing, in proportion as culture and civilisation has advanced; and any conclusions drawn from those which still remain in a wild state would be open to great objections, particularly as the question must necessarily embrace the nature of those no longer existing, but whose bones occur in a fossil state throughout Europe. We think it may fairly be presumed that, in all those convulsions which have agitated our globe, birds have suffered less than any other vertebrated animals. Their fossil remains are few, and of rare occurrence; while extensive deposits of bones and skeletons, belonging to quadrupeds, reptiles, and fish, occur more or less abundantly in almost every region, and attest the wide destruction to which such animals were exposed. It naturally follows that, in tracing the distribution of the feathered creation, we are left unshackled by geological controversy.

1173. *The few observations on the Ichthyology, Entomology, and Conchology of the Mediterranean* we shall hereafter make, in conjunction with those of Britain, will be found in unison with those features in the geographic distribution of birds we have already traced; and will equally evince the propriety of including the whole under one zoological division. This we propose to name the *European*. Such a designation is, indeed, somewhat objectionable, inasmuch as it embraces not only Europe, but Northern Africa and Western Asia: yet it will, perhaps, convey more definite ideas than if the name were adopted from the particular race of men belonging to these regions.

2. *The Mongolian or Asiatic Province.*

1174. *The birds of the Mongolian range* will be now adverted to. The typical nations of this variety of man occupy the remaining portion of the vast continent of Asia; while their characteristic peculiarities appear blended with the Malays in the more eastern islands of the Indian Archipelago. The ornithology of such a vast proportion of Asia is as varied as it is remarkable; but the very imperfect nature of the materials hitherto furnished for its elucidation, renders it impossible for us to give those satisfactory data which have been furnished by writers on the birds of Europe. Naturalists look forward with the greatest interest to the speedy termination of the zoological researches of General Hardwicke, as likely to supply these deficiencies. The vast stores of knowledge which a long residence in the East, and an ardent passion for natural history, have placed at the command of this naturalist, render him peculiarly qualified for such an undertaking.

1175. For our present purpose, minute detail is not, however, essential. Whatever doubts might at first have arisen on the propriety of considering Europe as the centre of an ornithological province, there can be none with respect to Asia. It is in these regions that the chief seat of the typical Gallinaceæ is placed; they abound in China, Thibet, the Indian Peninsula, and even extend to those islands which are considered the confines of the Mon-

80

THE SILVER PHEASANT.

the elegant Silver Pheasant (*Nycthemerus argentatus*) (fig. 80.), has been long domesticated in our aviaries. Three other superb species represent a group (*Lophophorus* Tem.), discovered only upon the continent. The whole of these Gallinaceous genera are totally unknown in Africa, Australia, or in the New World. When to these we add the Hornbills (*Buceridæ*), the Sun-birds (*Cinnyridæ*), the short-legged Thrushes (*G. Brachypus*), the short-tailed Thrushes (*Pittæ*), certain groups among the *Psittacidæ*, and many others totally unknown in Europe, Northern Africa, and Western Asia, yet abounding in the Mongolian nations, no further details appear necessary to mark the ornithological peculiarities of Asia, as distinct from those of Europe.

1176. From the Asiatic islands it would, perhaps, be more natural if we proceeded at once to notice the Malay or Australian range, as it is here that the Faunas of these divisions of the globe evidently meet. But as this would interfere with the order observed in the early portion of this essay, we shall pass from the northern regions of Asia to those of the New World; particularly as both present a mixed race of men, probably originating from the Asiatic continent.

3. The American Province.

1177. We proceed to a rapid sketch of American ornithology. It has already been shown that, excepting the Natatorial birds, there are fewer species common alike to Northern America and to Europe than might, perhaps, have been supposed; yet, were the proportion much greater, the circumstance would only prove that nature knows no abrupt distinction. It is not to the remote ramifications which she employs to connect her chain of operations that our attention is to be fixed; for they are too subtle to be unravelled by beings with faculties so limited. But as soon as she quits these inexplicable mazes, and again displays herself in a new but decided form, we may hope to gain some acquaintance with her laws. It is not, therefore, from either extremity of the New World that we must form our opinion on its zoological peculiarities. The ornithology of the Northern latitudes is evidently blended with that of Europe, and in all probability many of these species exist in Northern Asia; yet those of the more southern parts of America, beyond the Rio de la Plata and Paraguay, are nearly unknown. It is only within the last few years that the provinces, elevated on the Mexican Cordilleras, and now constituting a great republic, have been opened to the naturalist; and although, as yet, but superficially explored, there is perhaps no region in the New World which promises to yield more interesting facts, as connected with the animal geography of that hemisphere. Even the configuration of the continent, at the junction of its two great divisions, is typical of this distribution. It appears as if nature, elevated as on a throne upon this vast table land, 7200 feet above the level of the sea, had dispensed her forms to the right hand and to the left, retaining immediately around her a typical representation of every group. To the north she has given innumerable flocks of slender-billed insectivorous birds (*Sylvicolæ*, &c.), which annually depart to breed in those more temperate climes. These are accompanied by particular species of Flycatchers, Thrushes, Pigeons, and Hangnests (*Icterina*); the two latter in such countless numbers as to darken the air. To Southern America has been more particularly assigned the Macaws, Toucans, Scansorial Creepers (*Dendrocolaptes*), Ant Thrushes (*Myotherina*), Ground Doves (*Chamæpelis*), Tanagers (*Tanagra*), Trogons, Fruit-eaters (*Ampelidæ*), and the numerous and splendid race of Humming-birds. Yet of all these groups, save one (*Ampelidæ*), typical examples are concentrated on the table land of Mexico. These, moreover, are accompanied by some peculiar forms, not yet discovered in either portion of America, and by species among the natatorial tribes hitherto found only in the more northern latitudes.

1178. The typical Gallinaceous birds begin to show themselves adjoining the Equator, nearly in the same parallel of latitude as they occur in Asia: they belong, however, to distinct and

81

HUMMING BIRD.

peculiar types; as the genera *Meleagris*, *Crax*, *Penelope*, *Ourax*, *Phosphea*, *Ortalida*, and *Opisthocomus*. These find their representatives, for the most part, in the ancient continents, but not one species has been detected beyond the New World. A large collection of Mexican birds, now in the possession of John Taylor, Esq., F.R.S. &c., and which he obligingly submitted to our examination, have proved valuable materials to illustrate this part of our subject. The foregoing remark applies to the two great divisions of the *Simiæ*, or Monkeys, so accurately illustrated by those distinguished naturalists, MM. Cuvier and Geoffroy St. Hilaire.

1179. *The Melliphagous groups of America*, at the head of which shine the splendid family of Humming-birds (fig. 81.), form the chief peculiarity of its ornithology; other races, scarcely less beautiful, occur in Africa, Asia, and Australia: yet the natural genera are totally distinct. The number of species, and the variety of forms, among the frugivorous birds is another striking feature in the productions of the New World. Under this term we must include the richly coloured Chatterers (*Ampelidæ* Sw.) and Manakins (*Piprinæ* Sw.); together with the whole family of Tanagers (*Tanagrinae*), Hangnests (*Icterinae*), and Parrots (*Psittacidæ*). The first four belong solely to this continent, which more than any other abounds in vast forests of lofty trees, affording a perpetual and countless variety of fruits and berries, adapted to nourish all the families of hard and soft-billed frugivorous birds. If we turn to the other orders of vertebrated animals, the *Mollusca*, *Annulosæ*, or *Radiatæ*, each and all conspire to stamp certain peculiar features on the zoology of the New World, and to mark it as a distinct zoological empire.

4. *The Ethiopian or African Province.*

1180. *The chief seat of the Ethiopian variety* of our species is central Africa; while most writers agree in thinking that its northern limits do not pass the Great Desert. The pestilential atmosphere of tropical Africa has been an insuperable bar to the researches of Europeans; and all the ideas that can be formed on the zoology of such regions must be gathered from the partial gleanings made by travellers on the shores of Senegal and of Sierra Leone. The ornithological productions received from these districts evince a total dissimilarity from those of Northern Africa, but intimately accord, both in species and genera, with the ornithology of the south: to this, however, there are several exceptions. The Plantain-eaters (*Musophagidæ*), and the bristle-necked Thrushes (*Trichophorus* Tem.), are among the groups hitherto found only towards Sierra Leone. The Guinea Fowl, as its name implies, is most abundant in the interior of that country, where three species have been discovered. The common Bee-eater and the Golden Oriole are the only species among the land birds of Western Africa that occur in the European range; and these extend southward to the Cape of Good Hope. The whole extent of Africa south of the desert exhibits, in short, a marked difference in its ornithological groups and species from those belonging to Europe, Northern Africa, and Western Asia. The comparatively few exceptions of birds common to Europe and the Cape cannot diminish the general force of this remark, but merely shows that a few exceptions must never be taken as the groundwork of any particular theory. It is to one of the greatest ornithologists that France, or indeed any other nation, has produced, that we are indebted for the most perfect account of South African ornithology yet published; but it must ever be regretted that this portion of M. le Vaillant's labours terminated abruptly; leaving the Gallinaceous, Wading, and Swimming orders to be completed by some other, who, with equal enterprise and observation, should visit the same regions, and record their manners with the same veracity. Such a naturalist our own country has produced; and although an ardent thirst for knowledge has now taken him to the New World, we may yet hope that Mr. Burchell will give to science some further memorials of his African discoveries.

1181. *Between the ornithology of Africa and of America* there is, within the same parallels of latitude, a very strong analogy, although (in the sense which we apply the term) there is none of affinity. We know not, in short, a single perching bird common to both continents; although in the rapacious order, which among terrestrial birds are well known to have nearly the widest range, two or three species occur which likewise inhabit both extremities of Africa no less than Northern America.

1182. *The other vertebrated animals*, and the insects of Southern Africa, furnish similar results. On examining the large collection of insects formed by Mr. Burchell, in the territories of the Cape of Good Hope, we could not discover one out of many hundreds which was to be found in a much more considerable collection brought by us from South America, although many generic groups, particularly among the *Lepidoptera*, appeared common to both continents.

1183. *Between the faunas of Africa and America* the difference is unquestionably striking; yet there are several points of connection between the ornithology of Africa, Asia,

and Australia; and these appear not merely in generic groups, but even in species. The Drongo Shrikes (*G. Edolius*), the Larva-eaters (*G. Ceblepyris*), the typical Flycatchers (*G. Muscipata*, C.), the Crab-eaters (*G. Halcyon*), the Grakles (*Lamprotonis*), the African Saxicolæ, the two groups of tropical Finches (*Estrælda Amadina* Sw.), are all genera common to these three regions, — to neither of which, in a geographic division, can they be exclusively assigned. But we need not dwell further on such resemblances, which, after all, are but so many points of connection between geographic divisions, sufficiently distinct in their more prominent characters.

5. The Malay or Australian Province.

1184. The regions peopled by the Malay tribes is the last zoological division requiring elucidation. We have already adverted to the great diversity of tribes comprised under this variety of the human race, and the little authentic information yet collected concerning their origin or history. The zoological results, however, are more definite.

1185. On looking to the Indian Archipelago, as to that region where physiologists concur in thinking that the Malayan form is first apparent, we are told that several of these islands are peopled by two different races of men (*Lawrence*, p. 489. and *Cuvier*, p. 187.); the one frequently confined to the inland tracts, while the other people the maritime districts: their respective origins, however, are so little known, that it is still a matter of doubt which has usurped the territories of the other. (*Marsden's Sumatra*, 326, 327.) We confine these remarks to Sumatra and Java; for, with regard to the vast islands of Borneo, Celebes, and those smaller groups to the eastward, we know little or nothing of their productions or of their people.

1186. That the isthmus of Malacca and the adjacent islands exhibit the first indications of a peculiar race of people, is a fact upon which all writers appear to agree; and that we here begin to discern the indications of a new zoological region is equally certain: yet it would be altogether rash, with our present limited information, to hazard any theory which would respectively assign to these islands a definite character in its inhabitants or productions. But the zoology of Java and Sumatra have been of late so zealously and ably investigated not only by two distinguished British naturalists*, but by others† sent from France, that we shall in this place attempt to draw some results from their labours. The ornithology of these islands, with some few peculiarities, differs in no very decided manner from that of southern India. In both, the Gallinaceous genera, when they occur, are the same, although some of the Javanese species differ. Of the more typical *Sturnidæ*, common to the Old World, but as yet unknown to the Australian or Oceanic islands, no less than three inhabit Java. To these groups must be added, *Parus*, *Sitta*, *Bucco*, *Cursorius*, *Glareola*, *Buceros*, *Oriolus*, *Brachypus*, and many other genera characteristic of the ancient continents. The number of typical

82

MALACCOLOPHUS CONCRETUS.

Scansorial birds within the narrow limits of these two islands is truly remarkable. Eight species of *Picus* are described by Dr. Horsfield, and four or five others; one, the *Malaccolophus Concretus*, Sw. (*fig. 82.*), of a remarkably small size, have been sent to France by M. Diard.‡ The total absence of this family throughout the whole Australian range, is a circumstance in itself sufficiently strong to place the ornithology of Java and Sumatra beyond such limits; to which, nevertheless, it approximates very closely.

1187. The birds of Java and Sumatra, which indicate an approximation to the Australian province, belong to certain genera common to both regions; but unknown in Africa or India: these are, *Pitta*, *Centropus*, *Ocypterus*, *Prinea*, *Pogardus*, *Crateropus*, *Dacelo*, &c. In the Suctorial birds (the *Tenuirostres* of M. Cuvier), we find in Java an evident departure from the typical form of *Cinnyris* towards the *Melliphagida* of Australia, in the genus *Dicæum*; four of the known species being Javanese, and three Australian. What little is yet known of the birds of New Guinea, and its surrounding islands, exhibits a still greater deviation from the ornithological features of India. These enchanting regions, long the fairy-land of naturalists, remained nearly unknown until visited by learned Frenchmen, to one of whom has been assigned the distinguished honour of giving to the world the fruits of their scientific and important discoveries.§ It is in these islands that the *Melliphagous* genera begin to be

* Sir Stamford Raffles and Dr. Horsfield.

† MM. A. Duvaucel and Diard. By the untimely death of the first, an amiable and enthusiastic naturalist, France was deprived of talents which, even at an early age, were of no common promise. The rarest and most beautiful Javanese birds in the galleries of the Jardin des Plantes attest the zeal, and record the name, of M. Duvaucel.

‡ We believe this enterprising naturalist is still prosecuting his researches in the East. Again must we attest the liberality of a foreign nation in furthering the objects of this essay. When in Paris, we were allowed full and unrestrained permission to examine the *entire* collections of birds (whether arranged or not) made by M. Diard. The same permission was asked for those brought home by the late and lamented Sir S. Raffles, and deposited in the museum of the Zoological Society, but this permission was refused.

§ M. Lesson, *Voyage autour du Monde*, now in course of publication.

developed in the most novel forms, and the most sumptuous plumage. The grand *Promerops* of New Guinea can only be likened to the Australian *Ptiloris*. Several typical *Melliphagidæ* are in M. Lesson's collections. To these we can now add two species of genuine *Philedons** (Cuvier), and two of the genus *Vanga*. The group of which the *Muscicapa carinata* (Sw.)† is the type, displays itself in three new and beautiful birds, accurately described and figured by M. Lesson. The stay of the French naturalists on the coast of New Guinea was comparatively short, and their gleanings of its ornithology could not, from necessity, be otherwise than scanty; yet it is surprising that, among the birds thus procured, so large a proportion should belong to groups hitherto supposed peculiar to New Holland. It is clear, therefore, in a natural arrangement of ornithological geography, that the islands of New Guinea may be safely brought into that division which includes New Holland, New Zealand, and their dependencies: this distribution has, indeed, been generally adopted by geographers, merely from the relative positions of these islands.

1188. On the zoology of New Holland it is scarcely necessary, in this place, to expatiate. All naturalists concur in viewing this insular continent as the chief metropolis of a peculiar creation of animals; whose limits on one side we have already traced, and whose range on the other extends over the innumerable islands scattered in the great Pacific Ocean. The *Menura Superba* (fig. 83.) is the most remarkable gallinaceous bird of this range. The

MENURA SUPERBA.

Australian province is thus in full accordance with the distribution assigned to the Malay variety of our species: its connection with Asiatic zoology is unquestionable; but we have no means of judging into which of the three remaining divisions it blends, at its opposite extremity. Of the birds peculiar to those remote clusters of islands adjoining the north-west coast of America we are completely ignorant; nor are our materials sufficient to furnish even a plausible con-

jecture on the subject. Whether the Australian province, at its northern limits, unites again with the Asiatic, the American, or the European, must therefore be left to future discovery.

1189. We have now completed a general survey of the distribution of birds over the globe. The facts we have stated show the propriety of arranging the whole under five great divisions or provinces, which may be distinguished as the European, the Asiatic, the American, the African, and the Australian: each of these corresponds, with little variation, to the geographic distribution assigned by others to the different races of man. We must, therefore, now adopt one out of the two following conclusions: either that there is just and sufficient grounds for believing that the distribution of man and animals in general has been regulated by the same laws; or, that man and birds have been distributed alike, and all other animals differently. To us, at least, the latter conclusion appears highly improbable; not only as being unsupported by the least shadow of evidence, but as opposed to that harmony in creation, which is more apparent the more it is viewed in all its relations.

SECT. V. General Summary of the Subject.

1190. In offering these elucidations of a subject so vast in itself, and so important in all its bearings, it will be readily perceived that two different relations between animal groups are alluded to; one we have considered as of affinity, the other of analogy: and as the truth or fallacy of these views will mainly depend on the justness of these distinctions, a few observations upon them appear necessary. Naturalists, in general, have considered those resemblances which exist between certain groups placed in different regions, but in the same parallels of latitude, as indicating affinities; and on this supposition, as before stated, have framed theories by which animal geography has been divided into zones or provinces, limited more or less by certain degrees of latitude. It must be confessed that, upon a superficial view, there are many circumstances which appear to justify such a theory. Confining our attention to that department of nature which we have throughout selected, we shall partly recapitulate our former observations.

1191. The arctic regions, in one sense, may be considered an ornithological zone; for not only the same groups, but the same species, are found in such parts of Europe, America,

* We see no reason that, in the recent divisions proposed for the *Melliphagæ* of Lewin, the name of *Philedon*, given to these birds by M. Cuvier, should be obliterated. It is very questionable, at the best, to whom the priority of nomenclature belongs; because groups, in such a work as the *Règne Animal*, must of necessity be defined and printed long before they can be published. At all events, greater merit for the distinction belongs to a naturalist whose penetration enabled him to seize characters from external structure, than to him who had the living objects constantly before his eyes: for these reasons, we do not adopt the new name of *Tropidorrhynchus* (Vigors), but join the Continental naturalists in retaining *Philedon* (Cuvier) to that group of which the type is *Merops corniculatus* of Dr. Latham (White's Voy. pl. at p. 190.).

† Zoological Illustrations, vol. iii. pl. 147. Zool. Journ. i. p. 306.

and probably Asia, as enter within its limits. But, admitting this to the full extent, let us ask if these regions — by the number, variety, or peculiarity of their animals — are entitled to hold a primary rank with the great geographic groups already mentioned? Is there to be met with among the arctic birds numerous species which are not distributed far beyond such limits? Are there any generic or sub-generic groups which do not occur even towards the central parts of Europe, Asia, and America? These questions, which must be answered in the negative, sufficiently prove that the arctic regions do not possess the characteristics of a primary division; they must rather be looked upon as a point of junction, where the ornithology of the three northern continents blend and harmonise together.

1192. *The tropical regions of the Old and the New Worlds* have likewise been united in one province. How widely the ornithology of these countries really differs, has been already explained. True it is, that in numerous instances one group typifies another, as in the case of the American Humming-birds (*Trochilidæ*) being represented in the Old World by the Sun-birds (*Cinnyridæ*); and such relationship, in one sense, is certainly an affinity, inasmuch as in the natural system they appear to follow one another; but if we admit such a degree of affinity to be a sufficient guide to a distribution of birds, we must also do the same with regard to the varieties of man, since both appear dispersed upon the same plan. The red Indian of America as certainly represents the black negro of Africa as the latter does the sooty inhabitant of New Guinea; yet no one would think of classing them in the same race, merely because they inhabited countries under similar degrees of latitude. The dispersion of particular groups and of their species, upon the whole, is more in a longitudinal than in a latitudinal direction. This is exemplified in a remarkable manner by the migratory birds, which invariably proceed from north to south, or from south to north. It would, indeed, appear, that if animal distribution is to be regulated by geographic degrees, as accurate notions might result from making the divisions of longitude as of latitude: both, however, would be clearly artificial.

1193. *These parallel relations of analogy*, which every where present themselves in the animal kingdom, nevertheless deserve our greatest attention, as fraught with peculiar interest to the reflecting mind. There are throughout nature so many immediate and remote relations, so many unexplained ties of connection, that the most careful of her students are perpetually misled in attempting to trace her footsteps. In ordinary cases, the admirable distinction that has been drawn between affinity and analogy (*Hor. Ent.*) is, perhaps, the best that can be given; yet instances might be named, in which even this is totally inadequate to the end proposed: Natural relations are so complicated, that series of affinities apparently incontestable, will frequently, upon rigid analysis, turn out completely erroneous; proving no more than that nature, however diversified, presents so many points of general resemblance and of connection, that *partial* harmony will result even from a false combination of parts. Let us not therefore conclude, as is now too generally done, that by synthesis alone we can exhibit the true affinities of nature; that we may henceforward, without hesitation, assign to each of her productions its true station in the scale of being; that we have suddenly, and as if by magic, got full possession of that mighty secret which at once explains her laws, and expounds all that has perplexed the wise, and confounded the learned since science first dawned upon man. That the circular system is the nearest approach yet made to the *true* disposition which pervades nature, — a system which, from the perfections of its Creator, must be replete with order and beauty surpassing our utmost comprehension, — is indisputable, because none other has attempted to explain the relations of parts and the unity of the whole; but farther than this its pretensions must not be carried: it still involves questions of great weight, since by one theory the number of its primary divisions is stated to be *five*, while by another, founded on much more extensive analysis, it is maintained to be *three*. The searcher after truth will give to these his patient investigation, his cool and unprejudiced judgment: he may then hope to make one step nearer to truth; for science, in all ages, has ever remained most stationary when the advocates of any system have been most prejudiced.

1194. *It is with these qualifications* that the views here taken on the distribution of man and animals are given to the reader. It has been our desire to trace a connection, and a unity of plan, in both, and to simplify a subject hitherto involved in much intricacy. How far this object may have been attained, it is not for us to determine; but he who draws proofs of a Divine Creator from the harmony and design apparent in his works, has surely not written in vain.

CHAP. III.

GEOGRAPHY CONSIDERED IN ITS RELATION TO MAN IN SOCIETY.

1195. *Man, when considered not as a mere animal, but as a being endowed with thought, reason, and contrivance, capable of social intercourse and union, must be regarded as the most conspicuous object in the delineation of the globe. These attributes raise him to the first rank in this lower world; and in every region occupied and improved by him, the communities which he has formed become the most prominent characteristic; all other beings are there subordinate and subservient to him. The description therefore which, in the succeeding part of the work, will be given of the different regions of the globe, must be chiefly employed in delineating the aspects which man, as an active and social being, presents. At present, however, it would be premature to enter into the numerous details which this subject embraces. We can do little more than indicate the following general heads, under which it will be treated: — 1. Historical Geography. 2. Political Constitution of the different countries. 3. Productive Industry. 4. Civil and Social State of Man. 5. Languages.*

SECT. I. *Historical Geography.*

1196. *A survey of the history of man is necessary for enabling us accurately to understand, and duly to estimate his present condition. Not only inanimate nature, but even the animal and vegetable kingdoms, if left to themselves, would remain constantly in the same situation: the changes and modifications undergone by them have been produced entirely by man's interposition. That improved and civilised form under which he now appears, is the result of a continued succession of changes, which have been taking place from the earliest periods of authentic history. All the revolutions, both of ancient and modern times, have had a greater or less influence in producing the present moral, political, and social condition of man in the more improved quarters of the globe.*

SUBSECT. 1. *Ancient History.*

1197. *Ancient history is generally considered as comprehending the period which elapsed from the earliest authentic records, and particularly from the rise of the great monarchies, to the downfall of the Roman empire. The various forms which government and society assumed during that long period, though they were instrumental in preparing those which have existed in the modern world, did not bear any exact resemblance to them. Through the conquest of Rome by the barbarous nations, with which the first of these eras closed, almost every connection between them was cut off, except those of record and tradition.*

1198. *The rise of the great monarchies, Egypt, Assyria, and Babylon, constitutes the first grand epoch in ancient history. It nearly coincides with that of the great commercial republics, Tyre and Carthage. Human society, which had before existed in a very rude and imperfect shape, began to assume a regular, orderly, and even splendid character. All the arts which contribute to man's support and accommodation were carried to a considerable degree of improvement; and the foundation was laid of those intellectual attainments, which were to constitute his highest honour. Alphabetic writing was invented and widely diffused; the arts of painting, sculpture, and architecture, made a considerable progress; there were even formed some elements of science and philosophy. During this period, too, while the world generally was buried in the darkest superstition, a divine revelation, preparatory for another more perfect, having been first communicated to the patriarchs, was more formally disclosed to the legislator of the Jewish nation.*

1199. *The Persian empire embraced a wider extent of the globe than any that had previously existed, and comprehended those countries which had been most remarkable as the seats of improvement and civilisation. Although, however, it thus became instrumental in linking distant nations together, it bore chiefly the character of empty and barbarous pomp, and does not appear to have produced any material advance in knowledge and improvement.*

1200. *The rise of the Grecian States formed, perhaps, the proudest era in the history of the human race. The constitutions then formed afforded a degree of political liberty, and a developement of the higher energies of the human mind, which could not be attained in extensive empires, subjected to the arbitrary rule of a single individual. The military exploits of the Grecian people, by which they baffled the force of almost the whole known world united under the sway of Persia, were the most splendid that had hitherto illustrated the annals of mankind. Genius was exerted with nearly unrivalled power in every department; the historic page unfolded its utmost degree of energy and beauty; and many sublime lessons of morality were taught by the Grecian sages. The fine arts, poetry, painting, and architecture, reached an eminence which they have scarcely since regained, and in each the purest models were left for future imitation. After Greece had long maintained a glorious defensive war against Persia, her arms were directed to conquest. The reign and*

triumphs of Alexander, while they subverted her admired forms of civil polity, diffused her language, her arts, her knowledge, over a wide extent of the eastern world, and thus spread a circle of civilisation, the traces of which have never been wholly obliterated.

1201. *The dominion of Rome*, which succeeded and overpowered that of Greece, extended over a still greater variety of countries and people, than had been comprehended under any former empire. Her character, at first stern and austere, was gradually softened; and on arriving at her highest pinnacle of wealth and power, she made at the same time an unrivalled display of the pomp and refinement of polished life. She emulated, without fully equalling, what was most brilliant in the arts and intellectual attainments of Greece. But the most signal service which Rome rendered to the cause of civilisation, was by extending its empire over wide regions in northern and western Europe, which had previously been the seat of almost complete barbarism; though they now form the most enlightened and improved portion of the globe.

SUBJECT. 2. *Modern History.*

1202. *The downfall of the Roman Empire*, which marked the commencement of modern history, formed one of the most remarkable and disastrous eras in the destiny of the world. During the fourth and fifth centuries, a succession of barbarous hordes from Germany, Scandinavia, Russia, and even the remotest extremities of northern Asia, poured in upon civilised Europe, and exterminated or reduced to bondage the greater part of its people. All the arts and sciences, which had shed such a lustre on the Greek and Roman name, disappeared, leaving only some imperfect remnants, which were preserved in the depth of monasteries. The empire was partitioned into a number of disorderly little kingdoms, gradually merged into a few great monarchies, which, in their general outline, have continued to the present day. This era was also distinguished, in the East, by the introduction of the religion of Mohammed, and the rise of the Saracen power, which undertook, by force of arms, to diffuse that religion over the world. Its armed votaries overran a great part of Asia, Africa, and even of Europe, and continue still to maintain a powerful influence over the destinies of the human species. For some time, the states formed under this system presented a somewhat enlightened aspect, and even revived the expiring lamp of science; but the final issue of Moslem ascendancy has been, to diffuse through the world, ignorance, despotism, barbarism, and every principle hostile to human improvement.

1203. *The feudal system* was established gradually among the barbarous states formed out of the dismembered portions of the Roman empire. The king, or chief, distributed the territory among his nobles or followers, subject only to the condition of military service. These nobles, possessing almost uncontrolled jurisdiction within their own limits, holding at their disposal the services of numerous vassals, took advantage of every interval of weakness in the power of the sovereign, and rendered his power little more than nominal. They reduced the body of the people to a state of comparative slavery, waged numerous private wars with each other, and practised various robberies and extortions. During this turbulent era, all refined arts and pursuits languished, while, on the basis of ignorance, superstition erected an absolute and tyrannical dominion. The institutions of chivalry, however, which were then formed and gradually improved, introduced a sense of honour, and a dignity and refinement of manners, which have beneficially influenced modern society. This period was also marked by the piratical inroads of the Scandinavians or Northmen, who ravaged all the coasts of Europe, and obtained at least a temporary possession of considerable districts and even kingdoms. It was marked, lastly, by those memorable expeditions into the East, called the crusades, which, though attended with great extravagance, and occasioning much disaster and bloodshed, tended, on the whole, towards the improvement of European policy and social life.

1204. *The subversion of the feudal power, accompanied by the revival of knowledge, arts, and industry*, formed a most memorable era in the history of mankind. This change, which had been for several ages silently preparing, was carried into complete effect during the fifteenth and sixteenth centuries. The turbulent rule of the great nobles was then broken down, and was succeeded by several extensive but mildly administered monarchies, along with some free and commercial republics, and in one instance a limited constitutional monarchy. The reformation of religion eminently distinguished this period; but being opposed by the violent intolerance of the Catholic church, it gave rise to a series of dreadful and sanguinary struggles. A general activity prevailed throughout the whole sphere of human exertion. The revival of learning, the invention of printing, the extension of maritime enterprise, leading to the discovery of new regions, and of new routes to those formerly known, rendered the age peculiarly eventful and interesting. It derived, however, a somewhat disastrous character from the establishment of the Turkish empire in the East, by which the throne of the Greek emperors at Constantinople was finally subverted, and very serious alarms spread through the whole body of the European nations.

1205. *The modern system of polity* followed, as the result of the great changes which had taken place in the preceding period. During the seventeenth and eighteenth centuries, when

it prevailed, civilisation made very remarkable advances. The manners of social life became more polished and refined. The arts and sciences were carried nearer to perfection, and more widely diffused through the great body of mankind. Amicable relations, before unknown, were established between the different nations of Europe; fixed laws were agreed upon for regulating their intercourse; and war, when it did occur, was carried on with greatly diminished ferocity. The system of colonisation in the other quarters of the globe was also carried to a vast extent, particularly in America; and though its first establishment was attended with many circumstances of injustice and tyranny, it had the effect of bringing those quarters of the world into a more improved and civilised condition.

1206. *The era of political revolution*, which commenced towards the end of the eighteenth century, being that which is still in progress, cannot be characterised in so decided a manner. The formation of the great monarchies had delivered Europe from the turbulent sway of the feudal chieftains; yet the almost absolute power with which the sovereign was then invested, was found productive of many evils. The hereditary nobles, exchanging their rural seats for a residence in the great capitals, and indulging in ease and luxury, lost all influence over the body of the people. The diffusion of intelligence and wealth through the middling and, in some degree, even the lower ranks, was followed by a demand, on their part, to be admitted to some share in the administration of public affairs. This spirit, after fermenting for some time, and being diffused by the exertions of many distinguished writers, produced the French revolution, and the extraordinary series of events which have thence arisen. That great crisis did not merely agitate the interior of France, but by exposing it to foreign interference, and then impelling its own rulers to schemes of conquest, it changed for some time, in an extraordinary manner, the aspect of all Europe. Then, however, by a grand re-action, France was driven back within her original boundaries, and the political relations of the Continent were re-established nearly on their former footing. Considerable agitations, however, still prevail in the interior of different kingdoms, and their political constitutions have suffered, and are likely to suffer, material alterations.

SECT. II. *Political Constitution.*

1207. *The political constitution* under which any community subsists, forms a most important element in their social condition. Being usually established within certain local boundaries, and accompanied with a similarity in manners, religion, and other characteristic circumstances, it is the leading agent in constituting a country or state. In distributing, therefore, the four quarters of the globe into their smaller portions, the geographer uses chiefly political divisions. He finds states which have made any progress in civilisation arranged into kingdoms, empires, and republics. The elements of political power appear to consist of monarchy, aristocracy, and democracy; while the public functions, to be exercised within any state, are the executive, legislative, and judicial.

1208. *A kingdom* is a state of considerable though not vast extent, governed by a single person, as France, Spain, Prussia. The subjects are usually united by a similarity of language and manners, and pervaded by a national spirit. The power of the sovereign is commonly extensive, though controlled in some instances by national assemblies; and there is almost always a body of nobles possessed of high privileges and immunities.

1209. *An empire* generally consists of a number of detached kingdoms, which have been united by conquest under one head, as the Turkish, Persian, and Chinese. Being thus formed of an aggregation of different states, empires are usually of very great extent; and as military force has been the instrument of their combination, the sovereigns exercise almost always an unlimited authority. The different members having been brought into union by force only, rarely feel united by any national tie, and remain very dissimilar in manners, religion, and social institutions.

1210. *Republics* consist of states which own the supremacy of no king or sovereign, but are governed by a senate, an assembly of the people, or by both conjoined. Though these governments have acted a conspicuous part in the history of the world, they have been generally of small extent, consisting, in many instances, of not more than a single city, with a limited circle of territory. Where this form of government has been diffused over a great surface of country, it has consisted usually of a number of states, joined in a federal union. This is remarkably the case with the United States of America, where such a government has been introduced on a scale of greater magnitude than in any other quarter of the globe.

1211. *Monarchy*, among the elements which compose the political system, holds the most conspicuous place, and is the most generally prevalent. In some cases, the power of the monarch is wholly or very nearly absolute. In a majority of instances, however, it is more or less controlled by the influence of certain powerful and privileged bodies. In some constitutions the power of the monarch is combined with that of aristocratic and popular bodies, which share with the sovereign all the higher functions of government. These are called limited monarchies, and are now generally considered of all others best adapted for the preservation of a great people in a state of peace and prosperity. This form of govern-

ment, after being for a long time confined to Britain, is now spreading, though with some difficulty and confusion, over the rest of Europe.

1212. *Aristocracy*, or the power vested in a distinguished and privileged class, is found existing much less frequently as a distinct and decided form of government, than as an element combined with monarchy and democracy. Venice, perhaps, afforded almost the only example in which aristocracy subsisted for a series of ages pure and unmixed. In monarchies, the aristocracy consists of a body of nobility, possessing various gradations of personal and hereditary titles and rights; while in a republic it is formed into a deliberative body, or senate, exercising or sharing the powers of the state. In mixed monarchies, both these privileges are usually held by the nobles.

1213. *Democracy* is the name given to the government in which the sovereignty resides in the great body of the citizens. They exercise it, either in a general assembly of the whole nation, or by means of persons elected, during a certain period, to act for the body of their constituents. The former was the mode usual among the ancient republics; the latter is more prevalent in modern times, and is alone compatible with the great extent of territory occupied by the leading republics of the present day. Popular government has been very generally combined in a greater or less degree with aristocracy, though there seldom fails to be an almost incessant opposition between the two parties.

1214. *The legislative*, among the different functions of the body politic, is justly considered supreme; it establishes the laws and regulations, according to which all public affairs are to be administered, and to which the persons exercising the other functions are bound to conform. Countries in which the legislative as well as the executive power is exercised by one man, form absolute monarchies, where every thing depends upon the arbitrary will of that single individual. Even a purely aristocratic legislature is commonly felt to be severe and oppressive by the great body of the people. A government cannot be considered as free, unless the various classes of which the nation is composed have a voice in legislative arrangements. Those political systems, however, in which the laws are enacted by the whole body of the assembled people, are fitted only for a single city with a territory of limited extent. Of such a nature and scale were the ancient republics of Greece, and also that of Rome, during the earlier periods of her history. But when the whole of a great people are convened into one place, they form a mere tumultuary crowd, incapable of any regular or effectual exercise of legislative functions. This disadvantage has, among modern nations, been studiously remedied by the representative system, under which the inhabitants of each different district elect an individual understood to possess their confidence, who exercises in their stead the popular part of the legislative function. Upon this basis have been founded the British constitution, and others that have been considered as exhibiting the most perfect forms of civil polity.

1215. *The judicial power* provides for the security of person and property among all ranks of individuals composing the political body, and forms thus one of the arrangements most essential to general prosperity and well-being. The institutions for this purpose vary greatly in different nations and stages of society. Among very rude tribes, the individual has only his own strength and that of his kindred to aid in repelling aggression. As society advances, the administration of justice between man and man becomes a leading object of public concern. In the earlier forms of polity, however, the executive and legislative functions are usually blended; the monarch, or his deputy, sits on the tribunal of judgment, and the forms of procedure are exceedingly simple. The parties appear, and plead their cause *vivâ voce*; while the judge decides promptly and on the spot. In the further progress of improvement, it is discovered that this branch of public economy cannot be duly executed, without being entirely separated from the legislative and judicial departments, and made independent of them. Hence arise the different orders, judges, lawyers, and agents, by whom the different stages of procedure are conducted; written and voluminous codes of law are formed, with the view of providing for every particular case. Yet the expense and delay consequent upon these complicated arrangements sometimes cause the society to look back with regret on the simple and expeditious machinery employed by their rude ancestors.

1216. *Other important particulars* are comprehended in the political state of a society: — the *titles of nobility*, and the badges of honour and distinction among individuals; the *military and naval force* employed in the defence of a country; the *elements* which compose it; and the manner in which these are arranged and directed. The same subject embraces also the *revenue*, its amount, the sources whence it is derived, and the manner in which it is levied and expended.

SECT. III. *Productive Industry.*

1217. *The industry* of a nation is employed in producing the necessities, the conveniences, the ornaments, and the luxuries of life — all that is comprehended under the name of *wealth*. It forms thus one of the most important constituents of their prosperity and well-being.

1218. *The sources of national wealth* are usually divided into three; agriculture, manu-

factures, and commerce: each of these is divisible into several distinct branches, nor can the catalogue be completed without including the two occupations of mining and fishing.

1219. *Agriculture*, including the means of procuring every part of the produce of land, or what land bears on its surface, is unquestionably the grand source of human subsistence and accommodation. Hence chiefly are derived the materials used in manufacture; the objects, in the exchange of which commerce consists. The modes in which support and the means of enjoyment are obtained from land may be divided into three; hunting, pasturage, and tillage, which last being the only form in which labour is employed upon the ground itself, is more specially considered as agriculture. The collection of the spontaneous fruits of the earth, being confined to a few tribes in the lowest stage of improvement, scarcely requires to be taken into consideration.

1220. *Hunting*, or the chase of wild animals, to obtain their flesh as food, and their skins as raiment, is the earliest and rudest mode of procuring human support. This employment requires art and contrivance as well as bold adventure; but is usually accompanied with rude and turbulent habits, and, combined with them, constitutes what is called the savage state. As culture advances, and the greater proportion of the soil is devoted to the plough, or to the support of tame animals, its range is greatly limited, and in a high state of cultivation becomes little more than the amusement of the opulent. The chase of the fur-bearing animals, however, still affords one of the most valuable materials of commerce.

1221. *Pasturage*, or the deriving of subsistence from herds and flocks, tamed and trained so as to be subservient to the use of man, forms a more improved and comfortable occupation than hunting. Peculiar habits of life usually distinguish nations subsisting solely by pasturage. They are often destitute of any fixed abodes, moving from place to place in large bands or encampments, living within their tents in patriarchal simplicity, but towards other nations practising on a great scale war and robbery. These habits constitute what is called the barbarous state, still prevalent among the Arabs, Tartars, and other nations occupying an extensive portion of the earth's surface.

1222. *Tillage*, or the culture of the soil by the processes of ploughing or sowing, is employed, by all the more improved nations, as the most efficacious means of drawing subsistence from the earth. In proportion to the general improvement which any people have attained, is usually the skill and diligence with which this most important art is practised. The community which derives its chief subsistence from the culture of the soil, merits generally, to a great extent, the character of civilised. Some of the oriental people, as the Hindoo and Chinese, practise this important art with an indefatigable industry applied to every available portion of their soil, which is scarcely to be paralleled elsewhere; but in Europe, and especially in Britain, the use of machinery, the skilful rotation of crops, and various improved processes, render the same measure of industry much more productive. The objects of culture vary exceedingly, and for the most part according to the varieties of soil and climate. Grain, the main staff of human subsistence, forms every where the most extensive and important object of tillage. Climate chiefly determines the grain cultivated in any particular region. In the tropical countries it is rice; in the best part of the temperate zone, wheat and barley; in the colder tracts, oats and rye. Of luxuries, wine and oil are the most grateful, and in the most general demand; they have their almost exclusive growth in the warmer tracts of the temperate zone. The delicate fruits, from which they are produced, do not flourish in the excessively luxuriant soil of the tropics. There, however, the fragrant aromatic plants, and those filled with rich and saccharine juices, produce valuable substances, which are eagerly sought after by the natives of less genial climates.

1223. *Fishery*, by which subsistence and wealth are derived from the waters, forms a peculiar branch of industry, which flourishes in every stage of society. Even the rudest savages, wherever their situation admits, conjoin it with hunting, as a means of affording an immediate supply to their wants. They practise it often with a great degree of diligence and contrivance; but the progress of industry leads to various processes for extending and improving this branch. By the operations of salting and drying, fish is rendered fit to be conveyed as merchandise to the most distant countries. Some of the great maritime nations send large fleets into remote seas, where they find situations favourable to this pursuit. The whale and the herring fisheries have, in this manner, been raised to the rank of great national concerns.

1224. *Mining*, or the extraction of valuable substances from beneath the surface of the earth, can be extensively practised only in a somewhat advanced state of human industry. Yet nature has lodged in these dark repositories objects the most essentially conducive to the use and comfort of mankind, and others which afford his most brilliant ornaments. Here are found the bright and attractive metals of gold and silver; there the solidly useful ores of iron and copper; here glitter the diamond, the ruby, and the amethyst; there extend vast beds of coal, lime, and freestone. Gold, the most precious of the metals, is often the most easily accessible; but we can scarcely give the name of mining to the operation by which the savage merely collects its grains in the sands of the rivers, or even

extracts it by pounding, when mechanically combined with other substances. But metals, in general, when lodged in the bowels of the earth, exist in the form of ore, intimately and even chemically united with other materials, from which they can be separated only by smelting, refining, and other elaborate and even scientific processes. From the toilsome nature of these operations, and from the gloomy depths in which they are conducted, it is often difficult to procure a supply of workmen; hence slaves and individuals condemned for crimes have been employed to a later period in this than in most other species of labour. Whatever skill may be employed in mining, it is necessarily a local occupation, nature having irregularly and almost capriciously distributed its objects over the different regions of the globe. Even the experiments made to discover whether metals are lodged in any particular spot, are often attended with considerable cost, and even peril.

1225. *Manufactures* may be regarded as a process by which man creates, as it were, a value for himself. He cannot, indeed, make any new substance; he can seldom even alter essentially the quality of that which is furnished to him; but he can altogether change its character and quality, can convert a rude and shapeless substance into one eminently conducive to benefit, convenience, or ornament. The excrescence shorn from an animal, the pod hanging from a shrub, objects in themselves neither useful nor beautiful, are converted into commodious and magnificent robes, adorned with the most brilliant tints. Almost every natural product requires to undergo some change before it is fitted for the use of civilised man. Grain must undergo the process of grinding and baking; the juice of the vine, that of fermentation; even animal food, that of cooking. But the name of manufacture is not given to these processes, nor to any which do not, to a material extent, increase the value of the substances on which they are employed. The various articles of clothing form the principal objects of manufacture; next to which rank stuffs for furniture, metallic implements, and utensils. Manufacturing skill and industry, carried to a certain extent, mark, beyond almost any other circumstance, the advance of a people in arts and civilisation. The savage usually employs unaltered the substances with which nature furnishes him. He feeds on the flesh of the animals which he has killed in the chase; he clothes himself in their skins; he consumes in their crude state the roots and herbs which the earth spontaneously affords. Even the nations which subsist by pasturage, and have made, perhaps, a certain progress in agriculture, though they have usually acquired a desire for articles of fine manufacture, prefer to obtain them from more industrious neighbours, in exchange for their own rude produce. The eastern empires, for the consumption of their courts and great men, produce a few articles of exquisite fineness and beauty by mere manual labour, without any capital or any machinery at all costly or complicated. It is in Europe, and pre-eminently in Britain, that the two principles, the division of labour and large capital employed in the construction of the most ingenious machines, have enabled the manufacturer to produce fabrics which, for abundance, elegance, and cheapness, have surpassed those of every other age or nation, and have found their way into all the markets of the globe.

1226. *Commerce*, the third grand source of national wealth, does not even aim at producing any new article, or altering the texture or quality of that in which it trafficks. It merely conveys it from a place in which it is superabundant, to another in which it is wanted. This sometimes confers an exchangeable value on that which previously had none; in every case, where judiciously exercised, it very considerably enhances the value attached to the article which it conveys from one place to another.

1227. *The home and the foreign trade* form the two great branches into which commerce is divided. The former, in consequence of each of its transactions being on a smaller scale, and affording little scope for brilliant adventure and splendid speculation, attracts, in general, less notice, and is considered of inferior political importance; yet it is proved by Smith to be by much the most extensive, as well as the most conducive to national prosperity. Its basis consists in the exchange between the country and the town, of the grain, cattle, and other raw produce of the one, for the varied commodities framed by the manufacturing industry of the other. Home trade is either coasting or inland, the former, where practicable, being preferred for bulky commodities, or those to be conveyed between distant parts of a kingdom; much of the interior commerce also passes along rivers and canals. Foreign trade has no limits but those of the habitable globe; and, for reasons similar to those just hinted at in another case, the more distant branches are considered generally as the most brilliant and important; while, in fact, the trade with the countries most closely contiguous, from its quicker returns, ranks highest in real amount and value. Unfortunately, it has been hitherto much fettered by the jealousy and rivalry between neighbouring nations, which make each imagine the prosperity of another to be gained at its expense, and every commodity received from them, to be so much abstracted from its own wealth. Although this illiberal system has somewhat abated, yet the consequence still is, that intercourse with distant colonial possessions is more sure and steady than with any power entirely foreign. The extensive capitals now possessed by some European powers, especially Britain, enable them to carry on the most extensive commerce with countries situated at the greatest distance, and even at the opposite extremity of the globe. In the interior, also, of the great

continents, there is a foreign trade by land, carried on by caravans, which are so numerous as to resemble armies, and proceed to an immense distance.

1228. *The instruments employed in conducting and facilitating commerce*, and which are chiefly shipping, roads, and canals, form the most important part of what is called the fixed capital of a country. Under the head of roads, the invention of railways, though yet only in its infancy, promises to facilitate, in a remarkable manner, the interior communications of the countries in which it is employed.

SECT. IV. *Civil and Social Condition of Man.*

1229. *The population*, or the number of individuals, of whom any community is composed, forms, if not the most important, at least the most prominent circumstance in its social condition, and one on which its magnitude, and its place in the scale of nations, intimately depend. The ancient statesmen considered the increase of the numbers of a people as one of the most important of national objects, with a view both to its prosperity in peace and its strength in war. Politicians of the present day take a different view of the subject; observing that population in all circumstances of tolerable peace and prosperity easily maintains itself on a level with the means of subsistence, has even a tendency to rise higher, and by its superabundance to produce a distressing degree of national poverty: they have withdrawn all encouragement to the multiplication of the species; some have even suggested schemes for checking its progress. Still it must be admitted to be desirable that the earth should contain as many rational and intelligent beings as can subsist upon it with ease and comfort.

1230. *The actual amount of the population* in any particular period or country, has been involved in considerable uncertainty. It is only in modern Europe, and in the United States of North America, and there very recently, that general or careful enumerations have been made. But in all the other quarters of the globe, the estimates are formed upon very vague observation, founded on the density with which, on a superficial view, the districts appear to be peopled.

1231. *A national character* is found to pervade every community. The particulars have been often exaggerated, fancifully delineated, and rashly and indiscriminately applied to individuals; but to a certain extent such a variation may be always traced between one people and another. The grand distinction, founded upon the progress of arts, letters, knowledge, and refinement, is into savage, barbarous, and civilised: the first being marked by the total absence of these improvements; the second, by the possession of them in only an imperfect and progressive degree; the third, by their having arrived at a certain maturity. The savage state prevails among the natives of America, and the islanders of the South Sea; the former, however, being now in a great measure supplanted by European colonists. The barbarous state is general throughout Africa, and extends over a great part of Asia. The civilised state is found in the great empires of Eastern Asia, and in a higher degree, as well as under different characters, among the nations of Europe. In these last, too, civilisation appears to continue in a progressive and advancing state, while over the rest of the world it is nearly stationary.

1232. *The religion* professed by any people is a remarkable and most important feature in their social condition. Religious opinions do not come directly under the cognizance of the geographer; but he is called upon to mark this, as a particular in which nations strikingly differ from each other. The inhabitants of the earth may, in regard to religion, be divided into three great classes,—Christian, Mahomedan, and Pagan. The first, as to numerical amount, does not exceed the second, and still falls short of the third; but the nations possessing it have acquired such an ascendancy in arts, social improvement, and political power, while their colonies have filled, and are multiplying over all the lately savage and unoccupied portions of the globe, that in all probability this faith will, in a few generations, be more widely diffused than any other. The Mahomedan nations, though in numbers they perhaps equal the last mentioned, and though they occupy a large proportion of the most fertile regions of the globe, are yet sunk into such a state of slavery and degradation, and so decidedly surpassed by the Christian people, that their sway is not likely to endure above two or three centuries. Of the Pagan religions, much the most numerous, and the only civilised, professors, are those attached to the kindred creeds of Brahma and Boodh, established, the one over the greater part of Indostan; the other in China and other continental kingdoms and insular territories of Eastern Asia. From their peculiar habits, and the immutable nature of their institutions, they are likely to adhere to these systems with greater pertinacity than the votaries of superstition in Africa, the South Sea, and other quarters, where the train of belief and observance, however fantastic, is of a slighter and looser texture.

1233. *The progress of knowledge* forms a most conspicuous chapter in the history of the human species: it follows generally that train of civilisation which we have already delineated. In surveying particular communities, various particulars connected with this subject are highly deserving of the attention of the geographer. Among these we may mention the most eminent philosophers, men of science, and authors who have flourished in

any nation, — the institutions formed for the promotion and advancement of science, — the degree in which knowledge is diffused throughout the community, — the establishments formed for public and private education.

1234. *The fine arts*, — which are intimately connected with the more elevated and intellectual part of man's nature, and of which the successful cultivation confers glory on a people, and polishes and improves their manners, — merit to be considered similarly, and under the same general heads, as their intellectual attainments.

1235. *There are various points of minor importance*, which yet are distinctive and characteristic of a people, and excite thus a just and natural curiosity. Such are the amusements in which they chiefly delight, the peculiar costume in which they are attired, the species of food on which they subsist, and the liquor by which they are exhilarated, as well as the mode in which these articles are prepared for their use.

SECT. V. *The Languages of the World.*

1236. *On the subjects now enumerated*, it has been judged sufficient to indicate their nature, and the light under which they will be treated, reserving the details for the succeeding part of the work, when they come to be considered successively in reference to the various regions of the globe. But there is one subject into which it will be expedient, even at the present stage, to enter more particularly.

1237. *Language* is one of the strongest characteristics by which nations are distinguished from each other; at the same time the dialects spoken by different communities, even when most widely dissimilar, display in many cases relations and alliances indicative of a common origin. There exist over the world classes of languages, each of which comprehends the speech of numerous people, and forms a tie between them, marking early relations and connections. Language thus acquires a character especially geographical, illustrating the origin and families of nations, and the connections between different countries. It will then be advantageous to consider, in a large and comprehensive view, first, the language spoken generally over the globe, and then those which prevail in its different quarters.

1238. *The languages by which the nations of the earth are distinguished*, and from which are derived the *names*, not only of its principal features, natural and artificial, but of its different regions, and of the *places* contained in them, constitute an important department of geography. When we contemplate those names in maps, a little reflection suffices to convince us that most of them are to be regarded, not as mere arbitrary or fortuitous appellations, but as terms of definite meaning, or as significant memorials of the people by whom they were imposed; and, in tracing those of ancient origin through the mutations they have undergone, we are compelled to summon history to the aid of geography, for the purpose of explaining them with reference to the great events which have, from time to time, altered the political, civil, and social condition of the nations composing the great family of mankind. Thus, without adverting to the rise, growth, and extinction of kingdoms and empires in Asia, we may observe, that the series of revolutions which ended in the overthrow of the Roman empire, and the foundation of the existing system of Europe on its ruins, is in nothing more remarkable than in the change which it contributed to produce in the greater part of the world, through the migration of nations; a change so absolute, that it has served to mark the distinction between ancient and modern history, ancient and modern geography, and ancient and modern languages. Of this change the geographer, equally with the historian, is at every step of his investigations reminded. *France*, for instance, commemorates in her modern name that branch of the Germanic family of nations who prevailed in *Gaul*; yet she retains, not less in her topographical vocabulary than in her language generally, unequivocal traces of Roman dominion; and we recognise, though strangely curtailed, the imperial appellations *Augustodunum* and *Aureliana*, in *Autun* and *Orleans*. *Italy* and *Spain*, preserving a semblance of their ancient names, exhibit similar instances of disfigurement in those of particular places: *Forum Julii* and *Cæsar-Augusta* survive in *Friuli* and *Saragossa*; but the *Trasimene* suggests a less classic reminiscence as the lake of *Perugia*; nor can the *Betis* and the *Durias* be recognised under the more sonorous names, the *Guadalquivir* and the *Guadalaviar* (the *great river* and the *white river*), conferred on them by the Arab conquerors of Spain. Appellatives, also derived from languages little known, whether ancient or modern, are liable to mutilation from the varying orthography of travellers; and we can no longer wonder at the confusion caused by French voyagers in this particular, when we call to mind the difference not only between foreign and vernacular names, but between their written and oral expression; as when a German spells his native country *Deutschland*, and pronounces it *Teytshland*; or a Persian writes for Persia *Irân*, and pronounces it *Eeraun*. But the different idioms of the human race claim our attention from far higher considerations than the mere naming of places or of countries; for geography, considered as an auxiliary to what has been emphatically called "the proper study of mankind," is principally valuable as combining, with a description of the earth, a view of the different branches of the great human family by whom such vast portions of it have been "replenished and subdued."

1239. *Ethnography* is the term which has been employed to designate this branch of geographical science. It distinguishes nations by their languages, and professes to class them in kingdoms, genera, species, and varieties; but this systematic arrangement is as yet far from being completed. Of the numerous languages that are or have been spoken on the earth, many are so imperfectly known that it is difficult to determine to what family they belong. For this and other reasons it has been deemed expedient by a modern writer, who appears to have collated the labours of his predecessors on the subject*, to adopt a geographical arrangement, and consider languages in their relation to the five great divisions of the globe; the *Asiatic*, the *European*, the *African*, the *Oceanic*, and the *American*. It is obvious, however, that the ethnographical and geographical limits of a nation and its language may be widely different; the Spanish and the British, for instance, extend ethnographically to the remotest regions of both the Indies. Adopting this arrangement, not only as most convenient in regard to a branch of knowledge still in its infancy, but as most suitable to a *geographical* treatise, we shall proceed, without pausing to discuss the merits of any particular theory, to offer, in this and subsequent parts of the present work, such a succinct view of the known languages of mankind as its just proportions will allow.

1240. *The distribution of languages into Shemitic, Hamitic, and Japhetic*, according to the scriptural account, seems however entitled to some notice, as being well warranted in relation to the early languages of the world, if we can reconcile our thoughts to an affinity of languages after their confusion, and the consequent dispersion of the human race. It has been placed in a striking point of view by the very able author of the "History of Maritime and Inland Discovery," in Dr. Lardner's *Cabinet Cyclopædia*; and a brief sketch of his observations may be useful as an introduction to an account of languages more strictly geographical.

1241. *On reference to the sacred records*, we find that in the order in which the generations of the sons of Noah are given, Japheth takes precedence of Ham and Shem, and is called the elder. This the learned writer we are now citing has not noticed; he has taken the names in the order which long and universal usage has sanctioned.

1242. "*The family of Shem*," he observes, "comprised the pastoral nations which were spread over the plains between the Euphrates and the shores of the Mediterranean, from Ararat to Arabia. The Hebrews themselves were of this stock; and the resemblance of their *language* with the Aramean, or ancient Syrian, and with Arabic, sufficiently proves the identity in race of what are called the *Semitic* nations. There is no difficulty in assigning to each of the sons of Shem his proper situation. Elam founded the kingdom of Elymeis; Assur, that of Assyria; and Aram, the kingdom of Aramea or Syria, a name still clearly preserved in that of Armenia. From Arphaxad were descended the Hebrews themselves, and the various tribes of Arabia; and this close affinity of origin was always manifest in the *language* and in the intimate correspondence of the two nations. Some of the names given by Moses to the children of Shem are still used in Arabia as local designations: thus there is still in that country a district called Havilah; and Uzal, the name given to Sana by the sacred historian, is not quite extinct.

1243. "*The descendants of Ham*," continues this learned writer, "constituted the most civilised and industrious nations of the Mosaic age. The sons of that patriarch were Cush, Mizraim, Phut, and Canaan. The name of *Ham* is identical with *Cham* or *Chamia*, by which Egypt has in all ages been called by its native inhabitants; and *Mizr* or *Mizraim* is the name by which the same country, or more probably the Delta, is still known by the Turks and Arabians." [We may add, that it is the name by which, in the original Hebrew, Egypt is called in the admonition that precedes the decalogue.] "The land of Phut appears to signify Libya in general; and the name Cush, though sometimes used vaguely, is obviously applied to the southern and eastern parts of Arabia. The names of Saba, Sabtah, Raamah, and Sheba, children of Cush, have long survived in the geography of Arabia. The posterity of Canaan rivalled the children of Mizraim in the early splendour of arts and cultivation. Though the Canaanites, properly speaking, and the Phœnicians, were separated from each other by Mount Carmel, yet, as the same spirit of industry animated both, they may in a general sense be considered as one people. The Phœnicians possessed the knowledge of the Egyptians, free from superstitious reluctance to venture upon the sea. Their local position naturally engaged them in commercial enterprise. Their chief cities, Tyre and Sidon, had reached the highest point of commercial opulence, when the first dawn of social polity was only commencing in Greece."

1244. *To Japheth, "the Japetus of the Greeks"*, this writer concurs with others in ascribing the superiority over the other sons of Noah, if not in the number of his descendants, in the extent of their possessions. All the Indo-Teutonic nations, stretching without interruption from the extremity of Western Europe, through the peninsula of India, to the isle of Ceylon, he considers as belonging to this common ancestor. The Turkish nation also, occupying the elevated countries of central Asia, boasts the same descent. Their own tra-

* Dr. Balbi, *Atlas Ethnographique du Globe*. Paris, 1826.

ditions accord with the Mosaic history; and indeed the affinities of language, which are still evident among all the nations of the Japhethian family, fully confirm the relation of the sacred writer: yet the meaning assigned to the patriarch's name in the Sanscrit language, *Yapati*, "lord of the earth," tells for nothing unless we can suppose the name Japheth to be thence derived.

1245. *To Gomer, the eldest of Japheth's sons*, is ascribed, on the authority of Josephus, the distinction of being ancestor of the Celts. Magog may have been the founder of some Scythian nation. Madai is recognised as the ancestor of the Medes. The posterity of Javan and Tubal, and Meshech and Tiras, may be traced from Ararat, always called Masis by its inhabitants, through Phrygia into Europe. Tubal and Meshech left their names to the Tibareni and Moschi, Armenian tribes, whose early emigrations appear to have extended into Mœsia. In like manner the Thracians may have owed their origin to Tiras.

1246. *That the progeny of Japheth peopled Europe*, seems apparent on another ground, which we shall explain, after mentioning the remaining branches of his posterity. Askkenaz, the son of Gomer, is thought to be that Ascanius whose name so frequently occurs in the ancient topography of Phrygia, and from whom probably the Euxine, at first the *Axine*, Sea derived its appellation. "In Togarmah," observes this writer, "we see the proper ancestor of the Armenian nation, and it is even asserted by the Turks."

1247. "*Javan was the Ion of the Greeks, the father of the Ionians*." In the names of his sons we find fresh proofs of the consistency of the Mosaic history. In Elishah we see the origin of Elis or Hellas. The name of Tarshish is supposed, with little foundation, to refer to Tarsus in Cilicia. Kittim is said to mean Cyprus; and Dodanim, or Rodanim, is understood to apply to the island Rhodes." Here we may remark, that the sacred text contains a most important record relative to the descendants of Japheth: "By these were the *isles* of the Gentiles divided in their lands, every one after his *tongue*, after their *families*, in their *nations*." Now, if the Oriental latitude of expression be allowed in this instance, the *isles* of the Gentiles must include not only the ISLES of the Mediterranean and other European seas, but the PENINSULÆ of *Asia Minor*, of *Greece*, of *Italy*, and of *Spain*.

1248. *To the Phœnicians* must be partly ascribed the discovery of those territories collectively called "The isles of the Gentiles," and the earliest intercourse with them. Unfortunately those early navigators have left no records of their discoveries; and the little we know of their enterprises is derived from Scripture, and from the scattered notices of the Greek and Latin authors. They were, as elsewhere observed, the pilots of Solomon's fleet; and as often as the fleets of Egypt are mentioned by ancient historians, we find them manned and guided by Phœnicians. Their commercial enterprises had contributed to augment the wealth of that kingdom, which had attained a high degree of social order and economy seven hundred years before the Greeks became acquainted with the use of money. The numerous colonies which they planted along the shores of the Euxine, the Mediterranean, and the Atlantic, beyond the Straits of Gibraltar, attest the extent of their early voyages. Those of Utica, Carthage, and Gades or Cadiz, were founded between twelve and eight hundred years before the Christian era; but the seas of the west were probably explored for ages before settlements were formed at such a distance from the parent state. Their geographical knowledge, even in the fabulous times of Greece, probably embraced as large a portion of the earth as that of the Romans in the time of Augustus; but, with the caution characteristic of a mercantile people, they forbore to communicate that knowledge to the rest of mankind. The silence of these descendants of Ham leaves us in uncertainty as to the progress of those of Japheth in peopling the *continent*, the *peninsulæ*, and the *isles* of Europe. In still deeper mystery is involved the descent of the negro tribes of Africa from the father of Canaan. Having thus briefly characterised the Shemitic, Hamitic, and Japhetic races, we leave to the consideration of the curious the theories that have been framed upon them in respect to the different idioms of mankind, and revert to the geographical arrangement which we proposed to adopt.

1249. *Separating all the known languages of the globe into five grand divisions*, we name them the *Asiatic*, the *European*, the *African*, the *Oceanic*, and the *American*, according to the part of the world in which they are spoken. Then tracing, according to the best authorities, the several languages by their affinities, we class those which appear to be sister idioms in one group, assigning to it a distinctive name; as the *Mongolian* family, the *Celtic* family, or the *Sanscrit* family, conformably, in most cases, to the name of the principal people of each of those families. But here a difficulty arises from the variance between geographic and ethnographic limits. Several nations included in one of these groups have dwelt from time immemorial at once in Asia, Africa, and Europe; others in regions partly European, partly Asiatic: to which part of the world then must the family be assigned to which those nations belong? Two reasons influence the decision; the historical importance of the people, and its mass, or relative number, as may be better understood from one or two examples.

1250. *That the Chaldeans, the Assyrians, the Arabs, the Hebrews*, and other nations of the great Shemitic family, were from the earliest times inhabitants of Western Asia, we know from the writings of Moses, with which the results of the most eminent philologists and arith-

meticians wonderfully agree. These nations, therefore, belong unquestionably to Asia; the comparison of the Gheez and Amharic vocabularies having demonstrated an indisputable affinity between the people of Abyssinia, who speak the idioms comprehended in the branch called Abyssinian: their languages also are classed in the Asiatic branch, though in all epochs, even anterior to historical tradition, those nations have dwelt in Africa.

1251. *The great mass of the Malay people* occupies almost all the isles of the Indian Archipelago, all those of Polynesia, and some of Australia. Hence we regard the Malay family as Oceanic, and class all the people characterised by this idiom as belonging to that great ethnographical group. Thus, besides the Malays of the peninsula of Malacca, whose settlement in the extremity of Asia is of no remote date, this division includes the Si Deïa or Formosans of Asia, and the Madecasses of the African isle Madagascar.

1252. *The Uralian nations* belong equally to Europe and Asia; because, from the little we know of them, they have inhabited, time out of mind, the north-east and east of Europe, and the north-west and west of Asia. Following the demarcation prescribed by M. Malte Brun, we find that the great mass of the Uralian or Finnish nations belongs to Europe. We therefore regard the Finnish family as European, and class among them all the ancient and modern nations who, from striking analogies in their respective idioms, seem to belong to them.

1253. *The Esquimaux* have from time immemorial extended over all the north of the New World; while the sedentary Chutchkis, who speak a language evidently related to the idioms of those American tribes, occupy only the extreme north-east of Asia. The Chutchkis we therefore consider as American colonies, and, following the precedent of Dr. Balbi, re-unite them as such to the other nations of America who form the family of the Esquimaux.

1254. *Under a perfect ethnographical arrangement*, the languages of the Indo-Germanic nations, extending from Ceylon and the Ganges to the extreme west of Europe, and even to Iceland, would form, not a single family, but rather an ethnographic kingdom divided into six families.

1255. *In subsequent parts of this work*, the languages of the earth will be considered as divided into five principal branches: the *European*, the *Asiatic*, the *African*, the *American*, and the *Oceanic*.

PART III.

GEOGRAPHY CONSIDERED IN RELATION TO THE VARIOUS REGIONS OF THE GLOBE.

1256. *In the second part of this work*, the principles of geography have been treated of as founded upon a general survey of the globe. The most extensive portion of our task still remains. We must delineate the leading objects of nature, art, and human life, as they appear successively in each different region into which the earth is divided.

1257. *Five great general divisions of the earth* are now usually recognised: — 1. Europe. 2. Asia. 3. Africa. 4. America. 5. The extensive and numerous islands of the South Sea, to which the French give the name of Oceania, the English those of Australasia and Polynesia, to which we may add the islands of the Polar Sea. Each of these will form the subject of a separate book.

BOOK I.

EUROPE.

1258. *Europe* is the smallest in extent of the four great continents, and yet, without being liable to any suspicion of partiality, we may pronounce it the most important of all the divisions of the globe. Asia, indeed, was the cradle of civilisation and knowledge; but her empires soon became, and have ever since continued, stationary; while Europe has carried the sciences, arts, and refinement, with almost uninterrupted progress, to the comparatively elevated state at which they have now arrived. All the branches of industry are conducted with a skill and to an extent unattained in any other part of the earth. European vessels carry on the commerce of the most distant regions. The military and political influence of Europe is now of a magnitude with which the most powerful and populous empires of the other continents can no longer be compared. European colonists have now peopled, and

35 30 25 20 15 10 5 0 5 10 15

are *more and more* peopling, all the formerly savage and unoccupied quarters of the earth; and, with the exception of some strongholds of ancient and imperfect civilisation, the whole world is, through their influence, rapidly becoming civilised and European.

CHAP. I.

GENERAL SURVEY OF EUROPE.

1259. *Europe is bounded on the north by the Arctic Ocean, and on the west by the Atlantic.* On the south, the grand inlet of the Mediterranean divides it from Africa; and the Grecian Archipelago, with its subordinate branch, connected only by a narrow strait, the Euxine or Black Sea, divides it from a great part of Asia. Between the south-east extremity of the Black Sea and the Northern Ocean is an interval of 1400 or 1500 miles of land, forming the eastern boundary of Europe. Had this been known to the ancients, they would perhaps have identified Europe with Asia; but the separation is now too deeply marked, and is defined by too many characters, moral and political, ever to be altered. The absence of sea, the natural and most obvious boundary of a continent, has somewhat embarrassed modern geographers; for even a river limit is here wanting. The chain of the Urals, running from north to south, forms so important a feature, that it has been taken as the grand line of division; and is protracted to the Black Sea by means of continuous portions of great rivers Kama, Volga, and Don.

1260. *The form of this continent is singularly broken and varied.* While Asia, Africa, and the two Americas are each formed into a vast inland expanse, Europe is split into many distinct portions; peninsulas, large islands, and kingdoms, with extended and winding coasts. This form arises chiefly out of its inland seas, which penetrate farther, and are more

deeply embayed, than those of any other part of the globe. Numerous gulfs, scarcely secondary in magnitude and importance, branch out from them. The Mediterranean, which forms, as it were, a little ocean, separating Europe, Asia, and Africa, is connected with the Atlantic only by the celebrated Straits of Gibraltar, twenty miles in breadth. Its great enclosed branches of the Adriatic and the Black Sea penetrate, and render maritime, some of the most inland districts of the continent. In the north, the Baltic, with its great gulfs of Bothnia and Finland, is neither indeed so extensive nor so accessible; but it is of the highest commercial value, as affording a channel by which the rude necessities, the metals and woods of the north, may be exchanged for the wines, the silks, and other luxuries of the south. The British isles, by their varied configuration, enclose between themselves and the opposite continent several important seas and channels. We may add, that the mountains and the plains of Europe do not display those immense unbroken groups, or those level and almost endless expanses, which give so vast and monotonous a character to the interior regions of Asia and Africa. In general they are separated into smaller portions, and are happily and commodiously interchanged. They have kept Europe divided into a number of separate nations, holding easy intercourse. Probably, this relative position has been one great cause of that intellectual activity, and those vigorous exertions in all liberal and ingenious arts, which have raised this part of the globe to so high a pre-eminence. The immense inland plains of Russia and Poland, presenting an aspect wholly Asiatic, remained, even after the civilisation and improvement of all western Europe, sunk in the deepest barbarism, from which they are but slowly and with difficulty emerging.

SECT. I. *Natural Features.*

1261. *The surface of Europe*, as we have observed, is very diversified. Its mountains do not reach that stupendous height, nor stretch in such unbroken chains, as those of Asia and America: nevertheless, we may trace pretty distinctly two highlands, the northern and southern, and an intermediate lowland. The southern highland comprises the most elevated

mountains of the continent, the Alps and the Pyrenees connected together by the low chain of the Cevennes. Inferior branches from the Pyrenees extend through the Spanish peninsula; while from the Alps branch forth the Apennines, which range through all Italy, and spread their lower slopes over the greater part of southern Germany. The extremity of the Julian Alps, and the mountains of Dalmatia, connect the range with the great Turkish chains of Hæmus and Rhodope; parallel to which, though with a large group intervening, stretches the circuit of the Carpathian mountains. North of this, the great European lowland comprises the largest part of France, the south of England, the Netherlands, Northern Germany, all Poland, and the greater part of Russia. In the extreme north of Europe the mountainous character again prevails. The Dofrines reach through Scandinavia; while the north of England and nearly all Scotland is covered with mountains of secondary magnitude. Of all the European mountains the Alps are by much the highest, and perhaps may rank fourth to the Himalayah, the Andes, and Caucasus, among the mountain chains of the globe. Mont Blanc and Monte Rosa exceed 15,000 feet above the sea. The numerous other summits of this chain exemplify all the descending grades of elevation. The Apennines vary from 3000 to 6000 feet; but Ætna, at their utmost extremity, is nearly 11,000. The most elevated of the Pyrenees rises somewhat above that height. The Spanish summits are in general of the level of the Apennine, except the Guadarrama, which exceeds 8000 feet, and the Sierra Nevada, which equals the Pyrenees. The Thracian chains have not yet been subjected to survey; but they doubtless exceed those of Greece, which ascend to 6000 or 7000 feet. The Dofrines, notwithstanding their snowy and terrible aspect, are not of first-rate elevation. The great Norwegian chain does not quite reach 9000 feet; Ben Nevis is only 4300 feet; and none of the English mountains reach that altitude.

1262. *The rivers of Europe* are numerous, but none of them of the very first magnitude. The two largest flow through the great eastern plain, a semi-Asiatic region, and terminate in distant and interior seas, where they contribute little to commercial intercourse. The Volga, which alone can come into rivalry with the great rivers of Asia, passes the Asiatic limit, where it spreads into the great interior expanse of the Caspian. The Black Sea absorbs the other rivers from the great plain of Russia and Poland: it receives also the noble stream of the Danube, which belongs indeed to the central region of Europe; but directing its lower course through barbarous and uncultivated regions, and terminating in this distant receptacle, it conduces only in a secondary degree to the distribution of wealth and plenty through the continent. Western Europe is too much broken into separate portions, and crossed by high mountain barriers, to allow to its rivers a length of more than from 400 to 600 miles; and they have usually their entire course through a single country, — the Rhine, the Elbe, and the Oder, through Germany; the Loire, the Rhone, and the Garonne, through France; the Po through Italy; the Ebro, the Douro, the Tagus, and the Guadalquivir, through Spain. The northern rivers of Britain and Scandinavia, restricted to a still narrower field, seldom accomplish so long a course as 200 miles. Yet, though Europe does not present the grand rivers which distinguish the greater continents, it is on the whole happily and commodiously watered. Almost every part of it enjoys the benefit of river communication; it is neither overspread by the dreary swamps of America, nor the sandy deserts which render uninhabitable so great a part of Asia and Africa.

1263. *The lakes of Europe* are numerous, chiefly enclosed within its mountain regions; but few of them are of sufficient magnitude to rank as inland seas. Those alone entitled to this distinction are the Ladoga and the Onega, which, forming a sort of continuation of the Gulf of Finland, and being situated in bleak and frozen regions, minister very little to internal intercourse. Finland is covered with similar lakes. The Wener and Wetter of Sweden rank next in magnitude, and, surrounded by immense woods and iron mines, possess considerable beauty and value. Switzerland, with its Italian border, is the chief lake-region of Europe: its waters, particularly those of Geneva and Lucerne, enclosed between the loftiest snowy pinnacles of the Alps, present scenes of grandeur and beauty almost unrivalled; but they are not on such a scale or so situated as to afford any important inland navigation. Those of England and Ireland are merely small picturesque features. Those of Scotland are larger and more numerous; and a chain of them, having been connected by a broad canal, was expected to form a great naval route across the island.

1264. *The European soil* is distinguished for productions, perhaps surpassing in value those of any other quarter of the globe. It does not, indeed, possess that brilliant luxuriance of vegetation which adorns the equatorial regions of Asia and America. But corn and wine, the most substantial and most agreeable articles of human diet, are nowhere produced on so great a scale or in such high perfection. Grain, of one description or other, is raised over its whole surface, excepting in the extreme north; wines throughout all its southern kingdoms. In hemp, flax, and wool, those staple materials of clothing, Europe is equally pre-eminent. Silk, another valuable commodity, it produces copiously, though not so as to be independent of supplies from India and China. Cotton is the only great material which the immense manufactures of Europe derive almost entirely from the regions within the tropic. If we

except the horse and the camel, for which Asia is renowned, Europe contains the most valuable as well as the most numerous breeds of domestic animals. Its northern forests produce the finest timber in the world, with the exception of the teak; and its iron, the most useful of metals, surpasses that of the rest of the world: but all the more precious substances, gold, silver, pearls, jewels, exist in an extent so limited as scarcely to be deserving of mention. The cultivation of the soil is carried on with much greater diligence than in any countries except in the south east of Asia; while in science, skill, and the extent of capital employed upon it, European agriculture is quite unrivalled.

1265. *In manufacturing industry*, this quarter of the world has, within these few centuries, far surpassed all the others of the globe. Asia, indeed, has long boasted some fabrics of extraordinary beauty, — silks, muslins, carpets, and porcelain, — which are not yet altogether equalled: but the looms and workshops of Europe now yield a variety of fine and beautiful fabrics, in such profusion, and at so cheap a rate, as to place them within the reach of almost every class of society. This continent thus clothes all the young nations which have issued from her own bosom, and which fill nearly two entire quarters of the habitable earth.

1266. *Commerce*, on so great a scale as to connect together the distant quarters of the world, cannot be said to exist out of Europe. European vessels are found in the utmost bounds of Asia and America, in the snowy regions of either pole, and crowding the ports of the Austral continent. There is not now a place on earth, however remote, affording any scope for the employment of commercial capital, which is not immediately filled with the same promptitude as if it had been situated in the heart of Europe. The ships of that continent exceed those of all the others in number and dimensions: they are also the most skilfully constructed, and navigated by the only seamen who are qualified to guide a vessel across the great oceans. All these observations are liable to one slight exception: the new American states are beginning to form a commercial and maritime system, modelled on that of Europe — a system which, though existing yet on a very small scale, may one day, perhaps, surpass the original.

SECT. II. *Inhabitants.*

1267. *The population of Europe*, though more closely calculated than that of any other quarter of the globe, is yet far from being ascertained on data that are very precise. In regard to some districts, and in particular to the whole of the Turkish empire, no census has ever been instituted; in others the computation is founded only on the number of houses; and in some, ten, twenty, and thirty years have elapsed since any was attempted. The following is the best estimate which Hassel, in 1819, was able to make; but that of Balbi, in 1828, includes the result of various and more recent enumerations and estimates, though it is still probably in some respects defective: —

	Hassel.	Balbi.
European Russia	34,400,000	56,525,000
France	29,328,000	32,000,000
Austria	28,180,000	32,000,000
Great Britain	17,224,000	23,400,000
German States	12,058,000	13,246,000
Prussia	10,378,000	12,464,000
Spain	10,373,000	13,500,000
Turkey	7,500,000	9,500,000
The Two Sicilies	6,620,000	7,420,000
Netherlands	5,227,000	6,145,000
Sardinian States	3,975,000	4,300,000
Portugal	3,683,000	3,530,000
Sweden and Norway	3,468,000	3,806,000
States of the Church	2,374,000	2,500,000
Switzerland	1,729,000	1,980,000
Denmark	1,618,000	1,950,000
Tuscany	1,179,000	1,275,000
Parma, Lucca, Modena, San Marino	892,000	975,000
Cracow	96,000	111,000
	180,702,000	226,285,000

The chief discrepancy is in Russia, where Hassel has not included recent acquisitions; but Balbi has undoubtedly taken in part of Asiatic Russia. There is also a more recent census of Switzerland, of which Balbi does not seem to have been aware, which states its population above two millions.

1268. *The people of Europe* are divided chiefly into three great races, which differ, to a very marked degree, in language, political situation, and habits of life. These are the Slavonic, the Teutonic, and a third which Hassel calls the Romish, as occupying the chief of those countries which once composed the Western Empire.

1269. *The Slavonic races* cover the greater extent of Europe, since they occupy the whole of the eastern plain bordering on Asia, which it resembles. The people have a similar

resemblance to those of that continent; and were considered almost as beyond the social and political pale of Europe, till within the last half century. They have now forcibly thrust themselves into the European system, and rank among its most influential members. The Slavonic people consist of about twenty-five millions of Russians, ten millions of Poles, Lithuanians, and Letts, and about ten millions of other races, known under the uncouth names of Windes, Tcheches, Slawakes, Croats, Morlachians, which have found their way into eastern Germany, Hungary, and Illyria. Without wishing to consider intellectual and moral qualities as necessarily belonging to any particular race exclusively, we may notice it as a fact, that the Slavonians are, in both respects, less improved than other Europeans. They have only some infant forms of art and literature, which have sprung up from the imitation of those of the eastern nations. They are generally subjected to absolute monarchy, and the greater part of them are only beginning to emerge from the degrading condition of personal slavery. All the habits of life which connect them with polished society have been recently and studiously imported from the west, and are still intermingled with deep remnants of barbarism. The majority profess that superstitious form of Christianity acknowledged by the Greek church. Yet they are a brave, enterprising, and persevering race, and have established themselves as a ruling and conquering people, in reference to all the contiguous nations of Europe and Asia.

1270. *The Teutonic race* occupies generally the centre and north of Europe; besides Germany, their original seat, they have filled the greater part of Scandinavia, the Netherlands, and Great Britain, and may be reckoned at upwards of fifty millions. Under the limitations above stated, we may describe the Teutonic people generally as brave, hardy, intelligent, and industrious, though somewhat blunt and unpolished. All the sciences, and even the arts, both useful and ornamental, have been carried among them to the highest perfection; yet they are accused of wanting some of the graces and *agrémens* which embellish the courts and fashionable circles of the south, by whom they are treated as semi-barbarians. A great majority of the Teutonic nations are Protestants; and that enlightened profession is in a great measure confined to them, and to the nations in the other parts of the world who have sprung from them.

1271. *The race called Romish*, which comprehends the modern inhabitants of France, Italy, and Spain, has only a very imperfect claim to that title. The Teutonic nations, in conquering these countries, poured into them a vast mass of their own population: but Roman manners and the Roman language had taken such deep root in countries which once constituted the main body of the western empire, that the latter forms still the chief basis of the dialects spoken in this part of Europe. The Romish were the most early civilised of the modern nations. They have carried the polish of manners and the cultivation of the elegant arts to a higher pitch than any other known nation. In solid energy and intelligence, they scarcely maintain their ground against the Teutonic nations, who despise them as servile, artificial, and effeminate. If France has fully vindicated herself from some of these reproaches, it has been after imbibing a copious infusion of northern ideas, especially from Britain, upon whose political system she has studied to model her own. The Roman Catholic is the ruling religion in all these countries, and has among them her metropolitan seat. Previously to the rise of the spirit of philosophy, it was bigoted and persecuting in the extreme; nor is this temper thoroughly banished from some of its dark and benighted regions.

1272. *Certain interesting and antique races* inhabit the rude and mountainous extremities of Europe. The *Celts* were the most numerous people, and at a period of high antiquity, the possessors of all Western Europe. Subdued and disarmed by the Romans, they rapidly declined when the falling empire could no longer protect them, and became the helpless victims of that mighty torrent of barbarous invasion which poured in from the remotest extremities of Europe and Asia. At this dreadful period they sought or found a refuge, partly in Ireland and the Highlands of Scotland, where they exist under the name of Gael; partly in Wales and Britany, where they are called Cymri; and partly in the north of Spain, where they are termed Basques. Ages of adversity have completely banished those tame and effeminate habits which rendered them the prey of the invader. They are now the most rough and hardy of all the races, and those among whom civilisation has made the least progress. Having retained their condition unaltered during so many ages, they cherish a fond attachment to antiquity, and trace their pedigree higher than any of the Romish or Teutonic nobles. They have a traditional poetry celebrating the exploits of their ancestors, to which they are fondly attached; but in general they have, in the rapid progress made by the more modern races, been left somewhat behind; though individual emigrants have raised themselves to eminence in every department. Hassel calculates the Gael at 3,720,000, which, from the last census of Ireland, must be much too low; the Cymri at 1,610,000; the Basques at 630,000. The *Greeks*, once the most illustrious of all the races, no longer plant their colonies along the shores of the Mediterranean, but still occupy their old seats, and are spread through different parts of the Turkish empire. Depressed by two thousand years of slavery, they had ceased to display those high attributes which excited the

admiration of mankind ; but the prospects of independence which they have now opened for themselves, afford some hope that they may regain their place in the scale of nations. Their number may be about 2,100,000. The *Jews*, that singularly interesting people, are spread through all Europe, but especially the eastern countries, Poland, Russia, and Turkey. They are supposed rather to exceed 2,000,000. The *Gipsies*, in an humbler sphere, are strangely scattered over all Europe to the supposed number of 340,000 ; a wild, roaming, demi-savage race, of unknown origin, but probably Asiatic rather than Egyptian.

1273. *Several Asiatic nations* have penetrated by conquest or migration into the east of Europe. These are chiefly Tartars, whom Hassel estimates at 3,250,000 heads. The most prominent branch is that of the Turks, the ruling people in the Ottoman empire, though they form in a few districts only the majority of the population. It seems doubtful, however, if all the Tartars who wander over the southern steppes of Russia can be considered as Asiatic in their origin. The Magyars, who, to the number of 3,000,000, prevail in Hungary and Transylvania, appear to be also Asiatic, or at least to have sprung from that most eastern border of European Russia, which can scarcely be distinguished from Asia.

1274. *The religion of Europe* is almost entirely monotheistic. A mere handful of pagans, the Samoiedes, are found in its north-eastern extremity, on the shores of the Icy Sea. Europe is almost entirely Christian ; and the small population of Mahomedans who have found their way into it consist of Asiatic races, Turks, and Tartars. The Jews, however generally diffused, have nowhere a national church, nor are they in any nation fully identified with the body of the people. The Christians of Europe are divided into three great churches, the Greek, the Latin, or Roman Catholic, and the Protestant.

1275. *The Greek or Eastern church*, which was that of the Constantinopolitan empire, was severed from the Latin by the great schism in the ninth century, caused by some abstruse questions respecting the nature and person of Christ. It is still professed by the modern Greeks, is the established religion of Russia, and has votaries in Hungary and all its appendant territories. Hassel reckons its numbers at 32,000,000 ; Malte-Brun at 50,000,000 — a strange discrepancy. We should think the former much nearer the truth, though perhaps somewhat under it. This religion, having been long prevalent among unenlightened and degraded nations, has become encumbered with empty pomp and childish ceremonies ; and many of its clergy are ill-informed and of irregular lives.

1276. *The Roman Catholic religion*, which reigned so long with supreme sway over Europe, embraces still a numerical majority of its people. In Italy, Spain, France, and the dominions of the house of Austria, it is dominant and almost exclusive. It still holds attached to it a large portion of the smaller states of Germany, and of the Cantons of Switzerland. The greater part of Ireland and of Russian Poland continue attached to it, without regard to the opposite systems supported by the state. That deep intolerance which gave birth to so many struggles in attempting to extirpate the Protestant faith, has been greatly mitigated, and, except in Italy and Spain, all professions enjoy an almost complete toleration. The number of Roman Catholics seems to be fairly estimated at between 90,000,000 and 100,000,000. The absolute authority of the Pope in matters of faith and worship, auricular confession, the prohibition of the Scriptures in the vulgar tongue, and a splendid ritual calculated to dazzle the eyes of the multitude, form the peculiar characters of the Roman Catholic system. The monstrous pretensions once advanced to excommunicate and depose kings, and to grant indulgences to commit crime, seem now to be generally withdrawn.

1277. *The Protestant or Reformed religion* raised its standard early in the fifteenth century, and made most rapid progress, especially in the north of Europe. It sought to purge Christianity from the superstitious observances which had enveloped it during many ages of darkness ; to introduce a more spiritual and simple form of worship ; to break up the institutions devoted to celibacy ; to deny human authority in matters of doctrine, and rest it solely on the foundation of Scripture. It had to maintain a dreadful struggle against the Romish see, which armed in its cause all the great monarchs of Europe ; and in France and Bohemia, after taking deep root, it was nearly extirpated. It has been finally established, however, in Great Britain, in the Netherlands, the north of Germany, and the Scandinavian peninsula. Notwithstanding its numerical inferiority, it now ranks among its votaries the most powerful, the most opulent, and the most intelligent nations of Europe and the globe. Its rejection of human authority and direct appeal to the Scriptures, has caused it to be split into numerous sects and divisions. The most prominent is into Lutherans and Calvinists ; the Lutherans retaining still many of the Romish rites and doctrines, to which, in every point, the Calvinists place themselves in the most decided opposition. The English church may be considered a sort of medium between the two, inclining nearer to the Lutheran. In the Protestant countries, numerous smaller sects have asserted the right of private judgment, on which the Reformation was founded. Among these are the Anabaptists, chiefly in Germany, the Netherlands, and England, whom Hassel perhaps under-rates at 240,000 ; Methodists and Quakers in Britain, estimated at 190,000 ; the Moravian brethren in Germany, 40,000. The Unit-

rians have an established church in Transylvania, comprising 40,000 souls, and are diffused, openly or secretly, through the other European countries, especially Britain.

1278. *In learning, art, science*, all the pursuits which develope the intellectual nature of man, which refine and enlarge his ideas, Europe has far surpassed every other continent. The empires of Southern and Eastern Asia alone have an ancient traditional literature, of which the remains are yet preserved. But, besides being now in a very decayed state, it never included any authentic history, sound philosophy, or accurate knowledge of nature. An extravagant though sometimes poetical mythology, proverbial maxims of wisdom, and a poetry replete with bold and hyperbolical images, compose almost its entire circle. The science of Europe has been employed with equal success in exploring the most distant regions of the universe, and in improving the condition of man in society. Astronomy, which elsewhere is a mere mass of superstition and wild conjecture, has here not only delineated with perfect precision the situation and movements of the heavenly bodies, but has disclosed numberless systems of worlds, of which without her aid the existence could never have been suspected. Chemistry, which was formerly a mere collection of empirical receipts and chimeras, is become a mighty science, which analyses the most secret operations of nature, and discovers important, and before unknown, substances. A similarly sound and comprehensive character marks her attainments in physical science, and in every branch of natural history. In regard to poetic fancy, although some natural flights may be found among the rudest tribes, and though the Orientals possess a peculiar vein of learned and studied ornament, it is in Europe, during either ancient or modern times, that the polished and classic models of poetical composition have been exclusively produced.

1279. *The invention of printing*, and the consequent general diffusion of information among all classes, are features especially European. By their means, in its enlightened countries, the essential branches of knowledge are now placed within the reach of the humblest classes, and even the highest are not absolutely beyond their attainment. The endowments for the support of learning are very extensive, founded in a great measure during the middle ages, and bearing some stamp of the then infant state of literature; but they are now adapting themselves to modern improvements. The extensive and extending institutions for the instruction of the lower orders have produced a general diffusion of intelligence, to which in the other parts of the world there is nothing analogous.

1280. *The political state of Europe is also peculiarly fortunate*. Elsewhere a turbulent anarchy prevails, or vast empires are subjected to the absolute sway of a single despot. It is in this continent only that the secret has been found of establishing a regular and constitutional liberty, in which the extremes of tyranny and licentiousness are equally avoided. Even the absolute monarchies are generally administered with mildness, according to legal forms, and afford to the bulk of the people a tolerable security of person and property. The European states have also established among themselves a balance of power, which sets bounds to the encroachments of any particular state, and has repeatedly rescued the whole continent from the imminent danger of universal subjugation. This military and naval power has been raised to a height, to which none of the other continents can offer any effectual resistance. A great proportion of them has now been conquered, occupied, or colonised by Europe; and if the whole is not reduced under this condition, it is only through distance and extensive deserts that many great countries still preserve their independence.

1281. *The geology of Europe* will be more advantageously treated of under its respective countries.

SECT. III. Botany.

1282. *The botany of Europe* presents some general characters, which it may be important to notice. In the preliminary observations, we have given a very general and rapid sketch of the vegetable geography of the globe, taken in its more enlarged sense. We must now survey it in its subordinate divisions; and the plan which we have prescribed to ourselves, is, in the first instance, under the great principal divisions of the earth, to mention the more striking vegetable features; and then, under each respective country, to give a more particular statement of the plants belonging to it which deserve notice, either from their extreme abundance, their rarity, their peculiar properties and qualities, or some circumstance of general interest.

1283. The nature of the present publication only allowing us to consider, in a very general way, *the vegetable productions* as connected with their geographical distribution, we cannot devote much space to what concerns the primary divisions. The artificial boundaries of Europe, especially to the east and to the south, are of that nature that many of what might otherwise be ranked among its more striking botanical features are gradually blended into those of Asia on the one hand, and of the north of Africa on the other. The difficulty of speaking of the botany of Europe, exclusively of its neighbouring countries, is the less to be regretted, because we have already made remarks on the different regions of this and other parts of the globe, as indicated by the predominance of certain vegetables. Local circumstances, as we have there seen, affect the presence or absence of certain plants, to an extent more than equal to that of any artificial geographical arrangement. Tem-

perature, which has so powerful an effect upon them, varies in a regular progression upon a lofty mountain; but it is not so in all situations, and with the same regularity, especially on the great continents, upon the plains and low grounds. "Sometimes," says the eloquent Mirbel, "a chain of mountains forms a barrier against the freezing winds of the north*, and receives and refracts upon the plants the heat which it derives from the solar rays; sometimes a parching sirocco from the south raises the temperature; in some places, the winters are tempered by the proximity to the sea; whilst at other times all these causes combined, produce a climate so mild, that, to judge of its geographical position only by the indication of the thermometer, we should suppose its latitude to be much nearer the tropics than it actually is. Again, continued plains of vast extent, exactly on a level with the sea, are of rare occurrence; and if there be but an elevation of 1000 or 1100 feet, it suffices to produce a considerable reduction of temperature. This, in its turn, obtains an influence over the vegetable creation; it changes the line of the progress of plants in their migration; it arrests them, and limits their boundaries. Sometimes the northern species proceed southward towards the tropics; sometimes those of the south migrate northwards; and sometimes groups belonging to both of these tribes exchange countries, passing one another; each about to establish colonies in privileged stations, in the midst of a vegetable population to which they are no less strangers by their physiognomy than by their temperament."

1284. *Notwithstanding, however, the many anomalies which must exist in consequence of these and other circumstances of a similar nature, Europe being, to us especially, the most important division of the globe, the one with which we are most concerned, and being also that of which the botany has been best explored, we shall be pardoned if we enter a little more into detail with relation to it than to the other quarters of the world. But we shall confine, as much as possible, our observations to a most interesting table, by M. Mirbel, of the phænogamous (or flowering) plants of Europe; to which have been added, with great judgment, and for reasons already alluded to, part of those of Asia and of Northern Africa. We introduce this table with the more pleasure, because, the work in which it*

is inserted (Mémoires du Muséum d'Histoire Naturelle de Paris) being a foreign one, and both voluminous and very costly, it cannot be expected to be accessible to the general reader.

1285. *In the present instance, our author divides the northern hemisphere into imaginary belts or zones; the equatorial, the transition temperate, the temperate, the transition frozen, and the frozen zones. Wherever these zones are not interrupted by any natural limits, he compares them to the hues of the prism, which melt gradually one into another at their point of union; in such a manner as that the eye cannot separate them, though it distinguishes them perfectly. In what concerns the table in question, the equatorial transition, where European vegetation commences, is limited, to the north, by the disappearance of the Olive; the temperate zone by the cessation of the Oak; and the frozen transition by that of the Fir (*Pinus sylvestris*) in the west, and of the Spruce (*P. Abies*) in the east. The frozen zone is divided into two bands; the lower or southern, and the upper or northern. Both are entirely destitute of trees; but in the first band are many shrubs and suffruticose plants†: whilst in the second scarcely any thing is found but small*

BORASSUS. DATE TREE. DWARF PALM.

* A striking circumstance, corroborative of this fact, has been stated to us upon the most unquestionable authority: it is, that in one spot, in the extreme south of Sweden, facing the sea, and backed by lofty hills, *olives* have succeeded in the open air, and ripened their fruit; while, at the distance of six Swedish miles northward, the inhabitants clothe themselves with furs in the winter, to protect themselves from the severity of the cold.

† The shrubby or suffruticose plants of the southern band of the frozen zone, are fifteen willows: the Dwarf Birch (*Betula nana*), the Humble Birch (*B. pumila*), the White Birch (*B. alba*) — this last is only found on the southern coasts of Greenland; the Hoary Birch (*B. incana*), the Juniper (*Juniperus communis*), the

herbaceous plants; and these cease where the line of perpetual snow commences.* Here, too, another important fact must be considered, — that, in the frozen or arctic regions, almost exactly the same flora is exhibited in Europe, Asia, and America.

1286. In the extent of country to which the following table is more peculiarly applicable, the Dwarf Palm (*Chamærops humilis*), and the Date Tree (*Phoenix dactylifera*), (fig. 86.), are the plants that have the nearest approximation to a tropical vegetation, and which are,

of course, the most southern. The plant which is found the nearest to the pole, and which, there is every reason to believe, ascends to it, is the *Palmella nivalis* (Hooker, in Parry's Second and Third Voyages), the Red Snow (fig. 87.) of our arctic navigators, belonging to the Cryptogamic family, and which will be more especially noticed hereafter. In speaking of vegetation, however, generally, and except the contrary is otherwise expressed, the Cryptogamic plants are not taken into account; partly because we are at present but imperfectly acquainted with their extent or limits, and partly because they are not of such general interest.

Comparative Table of the phænogamous vegetation of a part of the *Temperate Transition Zone* (Palestine, Syria, Asia Minor, and the Caucasian regions; a portion of the north of Africa and the south of Europe being comprised in this zone); of the *Temperate Zone* (Central Europe as far as the Ural Mountains and the Caspian Sea, and parts of Tartary bordering upon that sea); of the *Transition Frozen Zone* (Northern Europe, Siberia, and Kamtschatka); and all the *Frozen Zone* (Polar Regions) of the Old and New World. Extracted from M. Mirbel's table.

	8193		3982		2129		438		10,292

In the temperate transition zone, out of 8193 species, 1262 have been ascertained to be woody, and 6898 herbaceous; and of these latter 3861 are known to have perennial, and 2373 annual or biennial roots.

* This solitary Cactus is introduced from America.

In the temperate zone, out of 3982 species, there are 357 woody, and 3625 herbaceous; of which 2610 are understood to have perennial, and 944 annual or biennial roots.

In the frozen transition zone, out of 2129 species, are 193 woody plants, and 1936 herbaceous; of which 511 are supposed to have perennial, and 363 annual or biennial roots.

In the frozen zone, of the 438 species, 46 are woody, and 392 herbaceous; of which 371 are estimated to have perennial roots, and only 15 annual or biennial roots.

1287. We have already stated that in the frozen or polar region the vegetation is very similar throughout the north of Europe, Asia, and America; which may in part arise from its limited extent, and from the continents approaching comparatively so near to each other. There must necessarily, too, be a greater equality of temperature than in the other zones; the vegetation every where appearing nearly upon a level with the sea. In Greenland, Schouw estimates that there is hardly one sixth of the plants that are not equally found in Lapland. Of the genera of Greenland only two are not found in Lapland (*Streptopus* and *Coptis*), and both occur in North America. We shall, by and by, notice how analogous is the vegetation discovered during Captain Parry's arctic voyages to that both of the European and American continents, in corresponding latitudes. Even in Kamtschatka, one half of the plants found by Wormskiold are European; and of the genera only eight or ten are not European, and they are North American. But, as we proceed from the Arctic Regions to the south, we find the vegetation gradually becoming more and more dissimilar between America and Europe; except, indeed, when the high mountains in the respective countries are examined, and then the resemblance again appears. Pursh, whose flora comprises, to a very limited extent, the plants of the arctic or sub-arctic regions, or of the lofty mountains of North America, but is principally confined to Canada, and to those districts of the United States whose latitude corresponds pretty nearly with that of the more temperate parts of the European continent, has about one seventh of his species only European; and if the doubtful natives, those *probably* introduced from the Old World, be taken into account, only one tenth: out of 716 genera of North American plants, 480, or two thirds, also occur in Europe, or in Northern Africa.

1288. Schouw estimates the most striking disparities between the vegetation of the western parts of the Old World, and the eastern parts of the New, to be as follows:—

1. The *Cruciform* (fig. 88. a) and *Umbelliferous families* (b): those of the *Pinks* (c) and *Labiæ* flowers (d) are much the most numerous on the old continent. The first, in North America, may be estimated at $\frac{1}{27}$, in Europe at about $\frac{1}{20}$; and the other families may be classed in the following proportions:—

	North America.	France.	Denmark.
Umbelliferous	$\frac{1}{34}$	$\frac{1}{21}$	$\frac{1}{23}$
Pink Family	$\frac{1}{34}$	$\frac{1}{23}$	$\frac{1}{21}$
Labiæ flowers	$\frac{1}{36}$	$\frac{1}{23}$	$\frac{1}{23}$

2. Of the family with *Compound flowers* (*Compositæ*), the groups of the Endives (e) (*Cichoraceæ*), and of the Artichokes and Thistles (*Cynarocephalæ*), are more abundant in Europe; whilst, on the other hand, North America possesses such a number of species of Michaelmas Daisy (*Aster*), and Golden Rod (*Solidago*), that they constitute one third of the compound flowers of that country, forming a striking feature in the vegetation of the United States, and carrying the preponderance in favour of North America.

3. The family of Bellflowers (f) (*Campanulacæ*) abound most in the Old World; that of the Cardinal Flowers (*Lobeliaceæ*), in the New.

4. Not a single species of Heath (g) is found in the new continent; while, in the old, immense tracts are covered with them; but their places are taken in America by the Whortleberries (*Vaccinia*).

5. Both in North America and in Europe, the forests are constituted by the families of

the Cone-bearing (*Coniferæ*) and Amentaceous (*Amentaceæ*) trees; but in America they far exceed those of Europe in respect to the number of species.

6. In North America we find the types or representatives of many tropical families; as, for example, of the *Cactuses*, *Scitamineous plants*, the Sago (*Cycadeæ*), the Custard Apples (*Annonaceæ*), the *Sapindaceous*, and the *Melastomaceous* plants: these are wholly wanting in similar latitudes in the Old World; and in regard to many others, which are common to both countries, such as the Palms, Laurels, Swallowworts (*Asclepiadeæ*), Sumachs, Cassias, and Mimosas, they are more abundant, and generally reach a higher northern latitude, in North America than in the Old World. In Europe, again, there are fewer arborescent plants; for, according to Humboldt, while North America has 137 trees whose trunks reach the height of 30 feet and upwards, Europe possesses only 45 of that character.

1289. *Siberia*, bounded as it is on the side of Europe by the Ural Mountains, differs from the latter country in a much less degree; and it is mostly in North American genera that this difference lies; as in the presence of the genus *Phlox*, *Mitella*, *Claytonia*, &c. and in the predominance of the tribes of Michaelmas Daisy (*Aster*), Golden Rod (*Solidago*), Meadow-Sweet (*Spiræa*), and especially of the Milkvetches (*Astragalus*) and Wormwoods (*Artemisia*), as well as (on account of the numerous saline lakes) the *Goosefoots* and *Saltworts*.

1290. *In the southern hemisphere*, the vegetation is very different from that of Europe in the corresponding degrees of latitude. In Southern Africa, Thunberg enumerates 118 species which are analogous to those of Europe; which would probably be found considerably to exceed the truth, if the species were accurately examined. Mr. Brown assures us that the Alpine Cat-tail Grass (*Phleum alpinum*) and the Moonwort Fern (*Botrychium lunaria*) exist in the Banksian herbarium, which were gathered in the extreme parts of South America: and the same accurate writer observed 45 European phænogamous plants in Terra Australis, of which 23 are dicotyledonous and 21 monocotyledonous, and 121 acotyledonous or Cryptogamia; namely, 2 of the Fern family, 25 Mosses, 14 Hepaticæ, 38 Lichens, 10 Fungi, 12 Algæ.* The very general distribution of plants of this class over the surface of the globe, we have before, indeed, had occasion to notice.

SECT. IV. Zoology.

1291. *The zoological features of Europe*, although sufficiently important to render this continent a primary division of geographic natural history, are neither so extensive nor so varied as those of more genial regions. We have already shown the propriety of including within this range the southern parts of Africa bordering the Great Desert; while the western provinces of Asia appear to partake both of the European and the Oriental zoology. It might be imagined that such a division, including countries suffering by the extremes of cold and heat, would present animals of the most diversified nature: but such is by no means the case, at least to any great extent. The chief seat of this zoological province appears to be on the southern side of Central Europe, towards the Alps, or those countries lying between the latitudes of 40° and 50° N.; as within these parallels the greatest proportionate number of species appear to be found. It may, however, be more natural to consider this zoological region as presenting three minor divisions: 1. The arctic; 2. The central; and, 3. The southern.

1292. *The arctic division* will include Greenland, the islands of Spitzbergen and Iceland, and a considerable part of Norway, Sweden, and Northern Russia. The *central* division may be said to commence towards the northern limits of Scotland, and to reach the shores of Northern Italy; or, more properly, to about the 45th degree of north latitude. The *southern* range includes the whole of the Mediterranean countries, Northern Africa, and Asia Minor.

1293. *The animals more particularly belonging to the arctic circle* are few in species. Those dreary and inhospitable regions afford but little sustenance to ruminating quadrupeds, or to insectivorous land birds; while the intense cold is as inimical to vegetation as to the production of insects. Yet these undisturbed solitudes are instinctively chosen by multitudes of marine animals, as secure retreats from the interruption of man, for breeding and providing for their young. The polar seas abound with innumerable water fowl; they congregate and build among the rocks, whose surface they almost cover by their numbers.

1294. *Of the Herring*, (*fig. 89.*) Pennant was among the first naturalists who believed that the countless myriads which annually visit the northern shores of Europe, migrated from the Arctic Ocean. The account given by this eloquent writer is so interesting, that we shall repeat it nearly in his own words:—"The great winter rendezvous of the herring is within the arctic circle. There they continue for many months, in order to recruit themselves after the fatigue of spawning; the seas within that space swarming with insect food in a degree far greater than in our warmer latitudes. Thus renovated, this mighty army begins to put itself in motion in the spring. They appear off the Shetland Isles in April and May: these are only the forerunners of the grand division, which comes in June; and their appearance is marked by certain signs, and

BRITISH HERRING.

* Of the 121 acotyledonous plants it may be observed, that all, except one, the *Marsilea quadrifolia*, are found in Great Britain.

by the numbers of birds which follow to prey upon them: but when the main body approaches, its breadth and its depth is such as to alter the appearance of the very ocean. It is divided into distinct columns, of five or six miles in length, and three or four in breadth; and they drive the water before them with a kind of rippling. Sometimes they sink for ten or fifteen minutes, then rise again to the surface, and, in bright weather, reflect a variety of splendid colours, like a field of the most precious gems."

1295. The migration of the herring, as related so circumstantially by Pennant, has, nevertheless, been questioned by other naturalists, who suppose that it is incapable of making such a rapid voyage in so short a time; and they further suppose that these fish, like the mackerel, merely seek refuge during winter in the depths of the ocean, and return to the shallower parts in spring, to deposit their spawn. A modern writer, indeed, confidently asserts that Pennant's account has no existence in nature; but we are by no means disposed to go such a length, considering

that there are many circumstances to be explained before a denial so unqualified can be implicitly admitted. That herrings may be occasionally found, at all seasons, about some of the European coasts, is by no means conclusive against the arctic retreat of the greater number; for among other animals, whose migratory nature is unquestionable, occasional stragglers are continually occurring in places far beyond their general haunts, and at seasons the most unusual.

1296. The zoology of arctic Europe has received much less attention than that of Northern America; we must, therefore, be somewhat concise on this head. Among the few original writers who have treated on the fauna of arctic Europe, the learned and acute Otho Fabricius, many years a resident in those dreary regions, deservedly ranks foremost. He enumerates thirty-two species of *Mammalia* as natives of Greenland, nine of which belong to the genera of Walrus and Seal (*Trichecus* and *Phoca*), and fifteen to the cetaceous

PTARMIGAN.

order; thus leaving but eight species of terrestrial quadrupeds, a proportion at once explained by the wild and desolate nature of these regions. The number of birds, comprehending such as are occasional visitors, amount to fifty-two. Seven of these are rapacious, and five are referable to the families of Warblers and Finches (*Sylviæ* and *Fringillidæ*); the remainder, with the solitary exception of the Ptarmigan (fig. 90.), or *Lagopus mutus*, belong to the wading and swimming orders, to whose nourishment and increase the arctic solitudes are particularly congenial. Nevertheless, by far the greater number of these birds occur abundantly in more southern latitudes; and many extend their flight to the warm shores

of the Mediterranean. Those species, in fact, which habitually live within the arctic circle, as if by preference, are remarkably few, and offer no good foundation to ground a belief that these regions constitute one of the primary groups in animal geography.

1297. The zoology of Central Europe may be said to commence towards the 60th degree of northern latitude, where a sensible change in the number and species of animals may be perceived; vegetation assumes a marked and decisive character; and those animals which depend for their support both on the produce of the earth and on the insect world are greatly increased, at once in number and in species. Vegetables furnish nutrition to insects,

THREE-TOED WOODPECKER.

and seeds to birds: the former, again, become the prey of the latter; and thus the supplies of nature are nicely and accurately balanced, with a just regard to the preservation of all her creatures. The dark pine forests of Norway, Sweden, and Lapland are the most northern boundaries of the Woodpeckers; one of which (*Apternus tridactylus* Sw.) is remarkable for having but three toes to its feet (fig. 91.), and is more peculiarly a native of these high latitudes. The insectivorous and omnivorous tribes begin, also, to be common; while the wading and natatorial birds diminish in numbers, though not in species; for as they congregate at certain seasons in the polar seas, so during winter they disperse themselves on the shores of Great Britain and the Continent. We have no very precise information as to the extreme northern range of those birds whose chief metropolis is in Central Europe; and we are still deficient in a Fauna Scotica.

1298. Most of the Arctic birds occur in the northern shores of Scotland, the islands of Orkney and Zetland, and on the coasts of Norway, Sweden, and Denmark. Müller, in his *Zoologia Danica*, enumerates 57 species of *Mammalia*, and 131 of birds, as natives of that kingdom. Among the former, 3 only are marine, and 14 are *Cetaceæ*: while the land birds amount to 87, exclusive of 26 belonging to the rapacious genera of Eagles, Falcons, and Owls. On comparing these numbers with those of the Greenland fauna, we observe, on the one hand, a considerable diminution of marine *Mammalia*, and a very large addition to the list of terrestrial birds; this latter circumstance is easily accounted for,—they are not formed to endure extreme cold; and being dependent upon insects and seeds for their support, their dispersion is naturally limited by the facilities afforded by nature for supporting life. Proceeding to those countries which lie towards the centre of Europe, there is a gradual augmentation of animal life: we may even trace this change in the local distribution of the animals peculiar to our own islands. Many species, in every department of zoology, are common in the southern and western counties of England, but which are totally unknown in the northern counties and in Scotland. The Red-backed Shrike breeds in the southern parts of Britain, but seems not to reach Scotland, where several of our most common summer visitors among the warblers and soft-billed birds appear to be equal strangers. The same may be said of nume-

rous insects and a variety of marine animals. Even among the domesticated races, a greater development of structure under a more genial climate is apparent in the Horse, the Sheep, and the Ox of Britain, when compared to those of the islands and mountains of Scotland; while among birds the gallinaceous genera, which, in our more southern climates, breed and live at all seasons in the open air, are reared and preserved with great difficulty in countries farther north; of these the Peacock and Guinea Fowl may be cited as examples.

1299. *The southern part of central Europe* is, then, the field best calculated for studying the peculiarities of European zoology. Commencing with the existing quadrupeds, we may remark, that while two species alone appear to inhabit the cold countries of Denmark, there are thirteen described as natives of France and the adjacent kingdoms, seven of which have been enumerated among British quadrupeds. The great white Bear, which is perhaps more truly an arctic animal than any other, disappears on the southern shores of the Polar Sea, and is replaced in temperate Europe by the common brown species, once a native of our own islands, and still found in the solitary seclusions of central Europe and Asia. Of this genus there are, according to Cuvier, but two recent species belonging to Europe, the brown (*fig. 92.*) and the black Bear. Others imagine, with some show of reason, that there are more; as the varieties from the first are very remarkable. The second is the black bear of Europe, differing from that of America in many important points of structure: only one living example appears to have been seen and dissected; and this, having died in confinement, afforded no clue to a knowledge of its haunts or manners.

92

BROWN EUROPEAN BEAR.

with the wolf, the only beast with which, by the vulgar, the animal they describe could be confounded. The wild cat is still said to be a native of Britain, and is spread over other kingdoms on the Continent. A recent author includes among the "extinct animals" of Britain the hyæna and tiger whose bones have been found in the caves of Kirkdale, as forming part of the modern geographic distribution of animals. This hypothesis no doubt is ingenious, but lies open to many and great objections. If such formidable and terrific carnivorous animals have existed in Europe since the last revolution of our globe, what others constituted their prey? Their food being flesh alone, what were the other races of quadrupeds destined by nature to furnish them with subsistence? These questions must be first considered, before we can assent to an opinion so confidently advanced. Whatever might have been the character of European zoology before the deluge, certain it is, that in its present state it exhibits that harmony and consistency which peculiarly marks a wise provision for all created things. As the number of European *Mammalia* are so disproportionably small, when compared with those of Asia, Africa, and America, so are the species which are to keep their own class under subjection feeble and few; and this law is not only apparent among quadrupeds, but is equally observable in every other division of animals. Now, as birds are much more numerous, we find that in addition to the natural enemies in their own class, there is a group of quadrupeds more particularly destructive to the feathered tribes. These are the *Mustelæ*, or Weasels; few perhaps in species, but important in their numbers, and in their powers of destruction. No less than eight species inhabit different parts of Europe. Like the monkeys of the tropics, many of them climb trees and suck eggs; and by thus destroying birds in every stage of life, from the egg to the adult, are peculiarly adapted to prevent an undue increase of numbers.

1301. *On the granivorous quadrupeds* it may be observed, that although the woods of Europe are deficient in that variety of pulpy fruits so abundant in tropical countries, and upon which the numerous monkeys, bats, and other animals of those regions principally

93

BEAVER.

live, yet there is a great diversity of nuts and grain. Hence we find a proportionate number of small quadrupeds, whose subsistence entirely depends upon these bountiful supplies of nature: under this head may be enumerated the Hedgehog, Squirrel, and the various Mice, of which seven species belong to Europe. The Beaver (*fig. 93.*), unknown now to our own fauna, appears recorded by our early historians as a British animal; and is still found in the vicinity of the Rhone, the Danube, the Rhine, and other of the larger European rivers. If naturalists are correct in considering

this to be identical with the American beaver, it is one of the very few instances of the same species of animal inhabiting the temperate parts of the old and the new continents. The black bear of Europe was long confounded with that of America; and a similar difference may possibly exist between the beavers of the two continents.

1302. *The different species of Mice, &c.*, now arranged under many genera, form an important part of European zoology; as will appear from the following list, furnished by Mr. Griffith from the valuable *Mammalogie* of M. Desmarest:—

Arvicola amphibius	-	Water Rat.	Mus musculus	-	-	House Mouse.
— arvalis	-	Field Mouse.	— messarius	-	-	Harvest ditto.
— fulvus	-	Fulvous ditto.	— minutus	-	-	Small ditto.
— argentoratensis	-	Strasburg ditto.	— agrarius	-	-	Setnic ditto.
Georychus Norvegicus	-	The Lemming.	— soricinus	-	-	Shrew-like ditto.
— terrestris	-	Land ditto.	— dichrurus	-	-	Particoloured Rat.
Mus sylvaticus	-	Field Mouse.	— islandicus	-	-	Iceland ditto.
— campestris	-	Plain ditto.				

The Hamsters, remarkable for their cheek pouches, and belonging to the same natural family as the mice, have their chief metropolis in Siberia; yet one species (*Cricetus vulgaris*) extends to central and northern Europe. The Marmots (*Arctomys Marmotta*, *Bobac*) are likewise nucivorous, and occur on the mountains of central and northern Europe, together with the *Spermophilus citillus*, or Soulsk of the Germans. Of the Hare, four species are European, the snowy, the common, the calling, and the rabbit; and these complete the list of European *Glires*.

1303. *Among ruminating quadrupeds*, the Elk and the Reindeer are well known inhabitants of the northern countries; the latter giving place to the Fallow-deer, the Stag, and the Roebuck, in the midland parts of Europe. In the lofty mountains and inaccessible precipices of the Alps and Pyrenees, the Chamois, Yzard, and Ibex still live in partial security, notwithstanding the daring intrepidity of their hunters. The Musmon is another European quadruped deserving particular notice, as being generally considered the origin of all our domestic breeds of sheep. It appears still to exist in a state of nature among the high mountains of Corsica and Sardinia; and although now extirpated upon the continent, is well ascertained to have formerly been common in the mountains of Asturia in Spain. Lastly, it appears incontestable that the ox, one of the most valuable of nature's gifts to man, originally existed in a wild state over the whole of Europe, but whether as a distinct species or mere variety is still uncertain. The white ox of Scotland is a peculiar breed, still preserved in some few parks of the nobility, and will be noticed hereafter. But a much larger race, distinguished by Hamilton Smith under the name of the Fossil Urus (*Griff. Cuv. iv. 414.*), although, probably, in existence long after the invasion of Cæsar, is now only known, like the elk of Ireland, by its gigantic bones.

1304. *From this brief enumeration of the European quadrupeds* it will be perceived that their numbers are too few, and their original dispersion too obscure, to allow of any correct notions being formed as to their natural distribution. With regard to the origin of our domestic animals, and the several races, breeds, or varieties that have apparently sprung from them, the reader must be referred to the writings of F. Cuvier, and the extensive researches of Hamilton Smith, whose acquaintance with the order of ruminating animals, more particularly, is, perhaps, superior to that of any other living zoologist.

1305. *The ornithological features* of the zoological province to which Europe belongs, have already claimed our attention. We shall, therefore, now merely notice a few

FULVOUS VULTURE.

circumstances connected with the ornithology of central Europe. On the highest summits of the Alps, and in the vast forests which clothe their sides in Hungary, Switzerland, and the Tyrol, are found all the four species of European Vultures: only one of these, *Vultur fulvus* (*fig. 94.*), appears to have a range in countries farther north; yet all are distributed over the southern kingdoms, and two are again met with on the northern limits of Africa and western Asia. The Iceland or gyr Falcon, long supposed to be peculiar to the high northern latitudes, is now considered the same with the *Falco candicans* of the northern parts of Germany. The wide geographic range of the rapacious order has already been adverted to; nor do we find any species besides the Vultures which serve to mark the ornithology of central Europe. The forests of Germany, Austria, Switzerland, and France appear to contain all the European Woodpeckers, which, notwithstanding their wide dispersion, are but thinly and partially scattered in the northern and southern kingdoms.

1306. *The range of the small insectivorous birds, or warblers*, requires much investigation; nor are we at this moment aware of any species in Germany which does not occur in France or towards northern Italy. The few gallinaceous birds of Europe are nearly all found towards its centre, although the different species of grouse seem to affect the more northern latitudes. The warm covering of feathers which protects their feet, is peculiarly adapted as

a defence from the intense cold of the polar regions. The Bustards, on the contrary, occupy the middle regions of Europe, and extend latitudinally from the confines of Asia to the shores of the Atlantic. The Bee-eater (*Merops apiaster*), the Roller, the Hoopoe, and the Golden Oriole, in their annual migrations from Africa, visit all the central parts of the Continent, but become progressively scarce as we advance northward.

1307. In the third portion of the European range, we comprehend the south of France, the whole of Spain, Italy, and Turkey, together with the coasts and islands of the Mediterranean Sea bordering Asia Minor and Northern Africa.

1308. On the geographic range of the quadrupeds more peculiar to these countries, little can be said; as the materials to be gathered from the relations of travellers unacquainted with zoology are generally most imperfect. There is no evidence of the great northern ruminating animals, such as the Elk and the Reindeer, being found wild in any of the countries which border the Mediterranean Sea, although a small species, probably the fallow deer or the roebuck, is represented as still to be met with in the extensive forests of Calabria. The Porcupine, now wild in those countries, is supposed (but with a slight show of reason) to have been introduced from Africa; but for what purpose we are uninformed. The Buffalo is domesticated in Greece and Turkey, and some parts of southern Italy; where it is sometimes, though rarely, used for draught.

1309. The ornithology of the countries bordering upon the Mediterranean presents many interesting peculiarities. The vultures, which are seldom found northward of the Alps, occur more frequently as the climate becomes warmer. This tribe appears to follow the course of the Apennines in Italy, and of the higher mountains of Spain and Greece, from whence they extend their range to Asia Minor and northern Africa. The Imperial Eagle (*Falco imperialis* Tem.) is chiefly found in southern Europe, while the Golden Eagle is much more numerous in the colder latitudes. The gigantic Owls of the polar regions are here unknown; but two or three horned species, of diminutive size, follow the migratory troops of smaller birds in their annual journeys across the Mediterranean. Two of these small owls have not yet been described. In the extensive family of the warblers, many appear peculiar to Italy, Spain, Sicily, and Sardinia; and in the latter island there has recently been discovered a second species of European Starling (*Sturnus unicolor* Tem.) (fig. 95.).

STURNUS UNICOLOR.

The grouse of northern Europe are rarely, if ever, seen. But two species of bustard (*Otis Tetrao* and *Houbara*) seldom met with farther north, are common in Spain, Italy, and Turkey. Here also we first meet with the African and Asiatic genera *Cursorius* and *Hemipodius*; birds which delight in the dry and arid plains of those continents, where they run with amazing swiftness. The rocky and uncultivated wastes of Spain, Turkey, and Asia Minor furnish two species of rock grouse (*Pterocles*) long confounded with that northern genus, of which it is the representative in warm climates. The beautiful Wall-creeper, with its bright rosy wings, although rare in other parts of

Europe, is not uncommon in Italy; while the Golden Oriole, the Bee-eater, the Hoopoe, and the Roller, four of the most beautiful European birds, are so abundant in the two Sicilies during the spring and autumnal migrations, that they may occasionally be seen hanging in the poulterers' shops of Naples and Palermo. The union of the African, European, and Asiatic ornithology on the coasts of the Mediterranean is further apparent among the water-birds. The Pelican, the Spoon-bill, and the Flamingo are still to be met with in these countries; although, from their large size attracting the sportsmen, they are never seen in any considerable numbers.

1310. The European reptiles are too few to afford any material illustration of animal distribution. The most remarkable forms and the greatest numerical proportion occur in southern Europe, particularly in Italy and Greece, and the islands of Sicily and Malta: some of these, as the Gecko, or house lizards of Naples and Sicily, belong to genera not met with farther north, but common on the opposite shores of Africa and Asia Minor.

1311. The fish and other marine animals of the Spanish and Portuguese coasts bordering on the Atlantic have not been well investigated, and our slight acquaintance with them is insufficient to give us any correct idea of their nature; but, on entering the Mediterranean, we find, at Gibraltar, many of those peculiar to much more southern latitudes. Spain and Portugal cannot be said, like England, France, or Holland, to have national fisheries; but no sooner do we pass Gibraltar, than these natural sources of prosperity and plenty are again opened to the industry and support of man. The enormous shoals of Anchovies (fig. 96.) annually employ, in their capture and preparation, a great number of

ANCHOVA.

persons: and the exportation of this highly flavoured little fish, to all parts of the world, creates an important branch of permanent commerce. The Herring and, we believe, the Pilchard, are not unknown in the fish-markets of Sicily and Malta; but, notwith-

standing their abundance in northern Europe, they are scarce in the Mediterranean, and never seen in any considerable numbers. The tunny fishery is peculiar to Sicily, although there is very little doubt that the same fish frequents the shores and islands of the Peloponnesus; yet the total disregard of the Turks to all sources of national wealth blinds them to this, and to every other advantage which Nature has placed within their grasp. The Ichthyology of southern Europe is certainly of a more marked and peculiar character than any other department of European zoology. It is at all times hazardous to venture upon numerical estimates, but it can be safely stated, that of nearly 150 species observed by us in the Mediterranean Sea, not more than one third belonged to the Ichthyology of Great Britain and northern Europe.

1312. *The Turtle of the Mediterranean* is that described by authors under the name of *Testudo caretta*: writers have uniformly copied each other in asserting that this is the same as the Loggerhead Turtle of the West Indies; and that its flesh is coarse, rank, oily, and not edible. The accuracy of both these statements may be questioned. Whatever may be

97

LOGGERHEAD TURTLE.

the qualities of the West Indian Loggerhead, we know, from personal experience, that the flesh of the Mediterranean species is delicious. We were once becalmed off the Isle of Elba, and in one morning captured a sufficient number of small turtle to supply the cabin table for a week. They made exquisite soup; and although one of the company was ill, it arose from repletion. We omitted to draw and describe the animal, from a belief that it was the Hawk's-bill Turtle, the only species described as inhabiting the Mediterranean; the figure given by Gottwold (fig. 97.) has been considered, by Dr. Shaw, as representing the *Testudo caretta*.

1313. *Of European insects*, a bare enumeration of the genera would alone fill a volume; and in the half-artificial, half-natural, arrangement in which our entomological systems at this moment remain, it is impossible to form any precise idea even on the natural distribution of the families. As we approach the provinces of southern Italy and the Peloponnesus, we find many genera which more properly characterise Western Asia and

98

CLEOPATRA'S BUTTERFLY.

Africa; while, in Sicily and Malta, the geodephagous groups, particularly the Linnæan *Carabii*, are diminished; apparently in species, but certainly in numbers. It is in these countries that the Ants, those universal scavengers of nature in tropical countries, begin to appear in almost every situation, and to perform those offices which in more temperate regions have been assigned to the *Geodephaga*, *Brachelytra*, and *Necrophaga* among coleopterous insects. Most of the northern Butterflies (*Papilionæ* Sw.) are common even in Sicily, where, notwithstanding a dissimilar vegetation and a more heated atmosphere, we find only three or four species unknown to the British fauna: among these, the *Gonepteryx Cleopatra* (fig. 98.), or Cleopatra's Butterfly, much resembles a British species, but has the middle of the anterior wings of a rich orange.

1314. *The Radiated animals* of the Mediterranean are particularly numerous; the many harbours, coves, and sub-immersed rocks, sheltered from those violent commotions which agitate the mighty Atlantic, afford them secure protection, and contribute to their rapid increase.

ANIMAL FLOWERS.

Their investigation, hitherto much neglected, offers a wide field for the discoveries of naturalists who can study them in their native seas. Numerous species of Sea Anemone, or animal flowers, unfold themselves in the crevices of the rocks; one of these (fig. 99.), ornamented with rich purple, is particularly common on all the shores of Sicily.

1315. *The tubular and cellular polypes*, whose habitations are termed corals and corallines, are generally abundant in warm latitudes. Among these a vast number of species occur on the shores of Sicily, Italy, and the Greek

islands, which do not inhabit the British coasts. Sicily, for many ages, has been celebrated for its fisheries of the true red coral (fig. 100.); and it still affords employment at certain seasons to many fishermen: but the produce of the old grounds of late years has materially diminished, through want of care and due preservation. The Bay of Naples likewise produces this beautiful substance, but the pieces usually found are small, and in no great abundance.

1316. *The Molluscous animals or shell fish* of southern Europe are in great variety; and are much more prized by all classes there, as general articles of food, than among us. This may, in part, be accounted for by the people being Catholics; and compelled, by the tenets of their religion, to abstain from meat twice a week, exclusive of the longer and more important fasts. Why, however, fish and cockles are not to

RED CORAL.

be termed meat, or animal food, does not exactly appear. Nature has given an abundant

101

SOLENI STRIGILATUS.

supply of both ; and although the Italians do not possess the British oyster, their seas produce a much greater variety in other species than we can boast of. It is no uncommon thing to see from twelve to fifteen different sorts of shell-fish, none of a small size, exposed in the principal market at Naples ; and we have been assured that double this number are not unfrequently served at the tables of the higher ecclesiastics and nobility of Tarentum during Lent, that city being highly celebrated for its shell-fish. The *Solen strigilatus* (fig. 101.) is abundant at Naples, and considered most delicate food.

1317. On comparing the conchology of the Mediterranean with that of Britain, there does not appear so much difference as at first might have been imagined ; nor are we aware of more than three or four genera in those southern latitudes of which examples have not been found in our own. Yet, on descending to species, the difference is much greater. Our limits would not permit an enumeration of such as are common to both seas ; but perhaps two thirds or three fifths of the Mediterranean shells have been found by our industrious conchologists in the Channel, and on the western or other coasts of Britain. The remaining portion indicate a strong affinity with the conchology of India and the Red Sea on one hand, and that of Africa, towards Senegal, on the other. The fluviatile species are most numerous in central Europe, where the heat of summer is less calculated to dry up those small pools and shallow streams, in which most of these univalve mollusca delight to dwell. The fluviatile bivalves are few ; but are of species which seem peculiar to the European range. Independently of those common alike to Britain and the Continent, there are others in France and the south of Europe (fig. 102). *Unio littoralis* (a) and the true *U. batava* (b) are common in the Seine ; and we have received another shell from near Gibraltar, which we suspect to be a new species, intermediate

RIVER BIVALVE SHELLS.

1320. These luminous animalcula adhered to whatever was wetted with the water, and continued to shine thereon ; the buckets, when shaken, appearing full of luminous particles. The water, examined by a microscope, was filled with little bodies, some roundish, some oblong, and generally about the size of a poppy-seed ; each of these had, at one end, a small navel-like opening, encircled by from six to nine delicate filaments which float within the bladder, and with which the animal seems to attach itself to other bodies, and to seize its nourishment. In the inside of these bladders there were many other small darker points, crowded together on one side, or here and there some larger ones, which might be either the remains of smaller animals which they had swallowed, or their own spawn. These globular animalcula (which Spix considers to be of the nature of Medusæ) have been named by Péron and Lechenault *Arethusa pelagica*, and by Savigny *Noctiluca miliaris*. They swim in greater or less numbers at night, but in the sunshine they appear to the naked eye like little drops of grease. When put into a vessel they soon die and fall to the bottom ; when they come near together, they appear involuntarily to attract each other, so that they form whole groups. The same phenomenon is sometimes observed in the day-time, when the sky is dark, which rarely happens : as these animals are seldom found in water taken up in the day-time, it is probable they then sink to the depths of the ocean, and only return near the surface towards night. (Spix, Trav.)

1321. Other luminous bodies resemble balls as large as a nut ; and every wave striking a ship, when filled with these animals, lights up all surrounding objects. Besides these, there are sometimes insulated luminous bladders, like fiery balls, a foot in diameter,

which rise singly above the water ; and the striking of two waves together produces a shallow bluish streak of light, resembling the reflection of lightning on the water. (Spix, Trav. l. 44. 47.)

1322. The quadrupeds of Europe, according to the most recent distribution of the species (Griff. Cuv.), under the modern divisions, comprise about ninety species, arranged under the following genera and sub-genera. To these must be added the fish-quadrupeds, or Cetaceæ, chiefly inhabiting the high northern latitudes : —

Bats.	Sorex - - - 8	Lutra - - - 1	Myoxus - - - 2	Hystrix - - - 1	Taurus - - - 2
Rhinolophus - - 2	Mygale - - - 2	Canis - - - 1	Mus - - - 8	Lepus - - - 3	
Plecotus - - - 1	Talpa - - - 1	Vulpes - - - 3	Cricetus - - - 2	Lagomys - - - 2	Marine.
Vespertilio - 13	Ursus - - - 2	Felis - - - 1	Gerbillus - - - 1	Cervus - - - 3	Phoca - - - 1
	Meles - - - 1	Lynx - - - 1	Aspalax - - - 1	Antelope - - - 1	Trichechus - 1
Land Quadrupeds.	Gulo - - - 1	Castor - - - 1	Arctomys - - - 5	Rupicapra - 1	Otaria - - - 1
Erinaceus - - - 2	Putorius - - 4	Arvicola - - 4	Sciurus - - - 2	Capra - - - 1	Mirounga - - 1
	Martes - - - 2	Georychus - 1	Pteromys - - 1	Ovis - - - 1	

1323. The genera of European birds, in reference to our former remarks on the geographic distribution of animals, deserves particular attention. Those marked * are typical of families or sub-families ; those † include sub-genera, or subordinate variations of structure to which we shall not attach a distinct patronymic name ; either because the higher groups have not been sufficiently analysed, or because these subordinate forms have been mistaken for genera. Decided stragglers are excluded ; other genera, of uncertain rank, are not marked. The typical genera of the wading birds have not yet been ascertained.

SECT. V. Languages.

1324. *Europe, considered in regard to its languages, comprehends the whole globe, through those immense colonies which have been founded by the nations of this continent in every other quarter of the world.*

1325. *The European languages, ancient and modern, form six families: — 1. The family of the Iberian languages; 2. That of the Celtic languages; 3. That of the Thraco-Pelasgic or Græco-Latin languages; 4. The family of the Germanic languages; 5. That of the Slavonic languages; 6. The family of the Uralian languages, commonly called the Finnish or Chudic.*

SUBJECT. 1.

1326. *The Iberian or Basque family has been divided into the two following branches: — 1. Ancient languages long extinct, under which are classed the idioms spoken by the Iberians in the greater part of the Spanish peninsula, in southern Gaul, and in some parts of Italy and its three great islands. 2. Ancient languages still living; of which the only one remaining is the Escuara or Basque, formerly spoken in a large portion of Spain and of southern Gaul, and now spoken only by the Vascongados or Basques in the Spanish provinces of Biscay and Navarre, and in some parts of the south of France. The Basques are the descendants of the ancient Vascones. Their language, which resembles no other European idiom, though it has adopted several Latin and some German words, appears to have a certain affinity to the Shemitic languages, and, in its conjugations, some analogy to the languages of America.*

SUBJECT. 2.

1327. *The Celtic family exhibits, like the Basque, two branches: — 1. Ancient languages long extinct, among which are classed the idioms spoken by the numerous Celtic nations in Gaul, in Belgium, in the British Isles, in parts of Germany, Italy, and also Galatia in Asia Minor. 2. Ancient languages still living, of which there are two: 1. The Gallic, Gaelic, or Celtic Proper, spoken in different dialects by the descendants of the true Celts, in a large portion of Ireland, in the Highlands of Scotland, in the Hebrides, and in the Isle of Man. 2. The Cambrian or Celto-Belgic, formerly spoken by the Cymri or Belgæ in Belgium and Britain, and now confined to a part of England and France. In this language are distinguished three principal dialects: the Welsh, spoken and written by the people of that name descended from the ancient Britons; the Cornish, formerly spoken throughout Cornwall, but extinct since about the middle of the last century; and the Bas-Breton, called also by French writers the Celto-Breton, spoken in the part of France formerly called Lower Bretagne, by the descendants of those British fugitives who, in the fifth century, sought refuge and settled in Armorica. The Bas-Breton has many sub-dialects and varieties.*

SUBJECT. 3.

1328. *The numerous family of the Græco-Latin languages may be divided into four branches: I. The Illyrian; II. The Etruscan; III. The Hellenic; IV. The Italic, including the Latin, the Romanic or Romano-Rustic, the modern Italian, the French, the Spanish or Castilian, the Portuguese, and the Valaque or Wallachian.*

1329. I. *The Thraco-Illyrian branch includes all those Thracian and Illyrian nations once seated in Asia Minor west of the river Halys, and in Europe all over its eastern portion, from Noricum, occupied by Celtic tribes, to the mouths of the Danube and the Dnieper, and even beyond. Of those nations, long extinct, or confounded with others, the principal were the Phrygians, the Trojans, the Bithynians, the Lydians, the Carians, the Lycians, the Cimmerii, the Tauri, the Thracians properly so called, the Mæsi, the Getæ, the Macedonians, the ancient Illyrians, among whom were the Dalmati and the Istri, the Pannonians or Pæones, the Veneti, and the Siculi. In this branch, according to M. Malte-Brun, may be not improperly placed —*

1330. *The Albanian, spoken in Albania and other countries by the Skipatar, named Arnauts by the Turks, and generally known under the name of Albanians. They form the principal population of Albania, and are scattered throughout European Turkey, especially in Roumelia, Bulgaria, and Macedonia; others on the Slavonic military confines of the Austrian empire, and others in various parts of the kingdom of the Two Sicilies. This Scyp, or Albanian language, according to M. Malte-Brun, appears to be formed of one third of ancient Greek, especially the Æolic dialect, one third Latin, one third of an idiom*

not yet ascertained, probably the Illyrian. The Albanians have three different alphabets: one sacred or hieratic, now fallen into disuse; another, the Greek alphabet; a third the modern Italian or Latin.

1331. II. *The Etruscan*, (we are here reminded of the *Osci* and *Heterosci*, quasi *Etrusci*?) spoken by the Etrurians, called also Tyrrhenians by the Greeks. This nation, according to some, appears to have been a mixture of Rhætian Celts with the Aborigines of Italy. The Etruscan alphabet was the same with the primitive alphabet of the Greeks; it had sixteen letters, and was written from right to left.

1332. III. *The Pelasgo-Hellenic*, including the idioms in ancient times spoken by the famous *Pelasgi* and *Hellenes*, long since incorporated with other nations. The people of early origin who may with probability be classed under this branch are, the *Pelasgi*, the *Leleges*, and other tribes enumerated by ancient geographers among the population of Greece and its isles, especially the *Græci*, originally a small community of Thessaly, but remarkable for having given name to the whole of that celebrated nation, whose language was —

1333. *The Hellenic*, or *ancient Greek*, formerly spoken in Greece and its dependencies, and at a later period in a great part of Sicily, Lower Italy, Asia Minor, Egypt, and its dependencies, in part of Gallia Narbonensis, and in other districts bordering on the Mediterranean.

1334. *During the Macedonian empire* the Hellenic was spoken at all the courts of the descendants of Alexander, and by persons of distinction in all the countries subject to the Macedonians. In a subsequent age, it was studied by all the most distinguished subjects of the Roman empire, and was the prevailing idiom in the East until the fall of Constantinople, at which period it was studied with renewed ardour in the West. In this language, 270 years before Christ, was written the famous version of the Hebrew Scriptures called the Septuagint; in this language also was the Gospel promulgated by the Apostles; and it thus became for ever sacred. It appears not the least wonderful among the dispensations of Providence, that the light of Christianity should have been originally diffused under the most powerful empire and in the most cultivated language of the ancient world, and that it should prevail notwithstanding the power of the one, and the learning and philosophy for which the other was so proudly distinguished. The literature of the Greeks, comprehending some of the finest productions of the human mind, is, perhaps, the richest in the world, and presents an unparalleled series of eminent writers, extending from the age of Homer to the middle of the fifteenth century. The language is one of the most flexible, harmonious, and copious that have ever existed; its grammatical forms are almost identical with those of the Latin, to the formation of which it has greatly contributed, but in many essential points it is superior, and especially in the unlimited faculty of making as many compounds as can be required. M. Malte-Brun distinguishes in the ancient Greek two different idioms: — 1. *The primitive Hellenic*, which he subdivides into three principal dialects — the Arcadian, the Thessalian, with the ancient Macedonian, and the Cœnotrian, transported into Italy and mingled with the Latin; 2. *The Hellenic of the historical times*, divided into four principal dialects and several varieties.

1335. III. *The Romaic*, or *modern Greek*, spoken by the Greeks of our own times, especially in the Morea, in Livadia, Thessaly, the isle of Candia, the Archipelago, part of Albania, Macedonia, Roumelia, Thrace, Asia Minor, Cyprus, and by the Greeks established in Wallachia, Moldavia, Syria, and Egypt. The Romaic is also spoken by the inhabitants of the Ionian Isles, by considerable numbers of Greeks in the Austrian and Russian empires, and some hundred of Mainotes in Corsica, near Ajaccio. It is divided into two principal dialects, the Romaic and the Æolo-Dorian, each including various sub-dialects.

1336. IV. *The Italic branch*, so called, as including the languages of the aborigines of Italy, which form the stem of the modern idioms comprised in this branch. Those *aborigines* were, the Euganei, the Ausones, the Lucani, the Brutti, the Piceni, the Marsi, the Latini, the Sabines, and the Samnites. From a mixture of the three last idioms, primarily with the original Hellenic, afterwards with the old Æolian and ancient Doric, was formed, as M. Malte-Brun inclines to think, the language spoken by the Romans, and called the Latin language. The languages included in that branch are, —

1337. *The Latin*, which was the written and current language of the higher classes in Italy and throughout the Roman empire. It was very different from the *lingua plebeia* or *rustica*, spoken in the rural districts of the peninsula, and by the lower classes in Spain, Gaul, and the other provinces. Its grammatical forms are similar to the Greek, though less perfect. Latin literature, formed on that of Greece, is very rich in all branches of knowledge, and, together with the Greek, is the source from which flows the literature of the modern nations of Europe. Its most brilliant epoch was the Augustan age. In this language St. Jerome wrote the Vulgate, or Latin translation of the Bible which is used in the Romish church. The overthrow of the Roman empire in the fifth century gave birth to a corrupt Latin, mingled with a great number of barbarous words, and named low Latin, which, until the fourteenth, was, almost exclusively, the written language throughout the West. In the two succeeding centuries, Latin literature again flourished, especially in Italy; but it was only to contribute to the improvement of modern languages, which being diligently

and successfully cultivated, the Latin was restricted to works of erudition alone. Its phraseology has had a marked influence on that of the most polite nations of Europe. It is now a dead language, except in Poland and Hungary, where some educated persons speak it in ordinary life with considerable purity, and with the Continental pronunciation, of course almost unintelligible to travellers from the English universities, who cannot or will not relinquish the Saxon diphthongal sounds of the vowels A, I, and U, the chief causes of their embarrassment. Latin is no longer employed except in the Catholic liturgy, in medicine, in the diplomacy of the court of Rome, and partially in the literature of all the civilised nations of Europe. The alphabet, of twenty-three letters, having been improved in its characters by the Italians and French, is used by all the people of Europe, except the Greeks, the Russians, and some other nations who have particular alphabets. This same Latin alphabet, with the Gothic forms it assumed under the pen of the writers of the middle ages, is used by the Germans and Danes, and by the Bohemians, and other Slavonic nations; and, according to some authors, its capital letters, truncated and squared to facilitate the inscription of them in wood or stone, constitute the Runic alphabet, formerly used in the north of Europe.

1338. *The Romana, or Romana Rustica*, spoken in the brightest ages of Rome by the lower classes in the south of the empire, excepting Greece, and some other countries. After various modifications more or less considerable it appears still to subsist among the vulgar dialects spoken throughout a great part of Spain, France, Switzerland, and some districts of Italy. The chief of those dialects, according to M. Champollion Figeac, are the following, classed with reference to those four regions:—In Spain, Sardinia, and the Balearic Isles, the Catalan, the Valencian, the Majorcan. In France, the Languedocian, the Provençal, the Dauphinois, the Lyonnais, the Auvergnat, the Limousin, and the Gascon. In Switzerland, the Romanic, or Celto-Romanic, (frequently called Romance, Churwelsh, and Rhætish,) the Valaisan in the Valais. In the states of the king of Sardinia are spoken the Savoisan; and the Vaudois in the vales of Lucerne, Perosa, and part of Piedmont. To these might be added the jargon call *lingua Franca*, in which Catalan, Limousin, Sicilian, and Arabic are the principal ingredients. The Romance literature is also called that of the Troubadours. From the mixture of this language with the different Germanic, Slavonic, and other idioms, were formed, in the tenth century, the following languages:—

1339. *The Italian*, spoken by the Italians in almost all Italy, in the isles geographically connected with that peninsula, and in various Alpine territories; also frequent in Dalmatia and the isle of Tino; very common at Constantinople, and in several mercantile towns of the Ottoman empire. The *written* language, which is nowhere *generally* spoken, is common with all well-educated Italians, and differs little from the vulgar tongue, which is subdivided into a great number of dialects. The principal of these are, the Piedmontese and Genoese; the Milanese, or Lombard proper; the Low Lombard; the Bolognese, the Bergamasc; the Venetian, the Friulian, the Tyrolean, the vulgar Tuscan; the Roman; the Sabine and Abruzzan; the Calabrian and Apulian; the Tarentine; the Neapolitan; the Sicilian, and the Sardinian.

1340. *The French language*, spoken by the French almost throughout the north of France; by the Walloons and Flemings in various Netherlandish provinces; by the Swiss, in several of their cantons; by the people of Jersey and Guernsey; also in some parts of the Austrian and Russian empires, and of the Prussian monarchy; by the French colonists in Asia, Africa, and America. In its infancy there were two idioms respectively designated by their word of affirmation, their “Yes,” the *langue d’oc*, which was used in the southern provinces, and the *langue d’oui* in the northern. This prevailed, and became the French tongue; the other was commemorated in the name of *Languedoc*, given to the province where it was most current. Without entering into farther detail respecting the French language, or analysing its structure, we may distinguish, after M. Champollion, the following as principal dialects:—the *Picard*, the *Flemish*, the *Norman*, the *Walloon* or *Rouchi*, the *vulgar French*, the *Breton French*, the *Champénois*, the *Lorraine*, the *Burgundian*, the *Franche-Comté*, the *Neufchâtelain*, the *Orléannois*, the *Angevin*, and the *Manceau*. To these might, perhaps, be added the jargon spoken by the negroes and creoles in the French West Indies.

1341. *The Spanish or Castilian language*, spoken by the Spaniards in the greater part of Spain, and, with some variation and admixture, by their descendants in Oceania, Africa, and America; also by the numerous Spanish Jews established in the Ottoman empire, and in other states of Europe, and of North Africa; in the isle of Trinidad belonging to the crown of Great Britain; in the Floridas and some part of Louisiana; and in the eastern part of Hispaniola or St. Domingo. This language is also common to all the inhabitants of the towns of Spain where the Basque and Romance languages are spoken. The written and polished language is almost identical in its grammatical forms with the Romance and the Portuguese; and differs little from the Italian; it is very rich and harmonious, notwithstanding some guttural and aspirate sounds taken from the Arabic, from which it has borrowed many words. It is singular to remark, that the *German* is characterised by similar gutturals or aspirates. The reigns of the emperor Charles V. and of his son Philip II. were the

golden age of Spanish literature; after which it fell into decay, but partially revived under the Bourbon kings Philip V. and Charles III. Of the dialects, which differ little from each other, the following are the principal:—the dialect of Toledo; that of Leon and the Asturias; the Andalusian; the Murcian; the Galician, or Gallego; and the Transatlantic, spoken in America; where, next to the English, the Spanish language is spoken by the greatest number of inhabitants.

1342. *The Portuguese language*, spoken by the Portuguese in Portugal and the Azores, and, with some differences, by the Portuguese Jews settled in Hamburg, Amsterdam, the Tyrol, and other parts of Europe, Asia, and Africa; also by the descendants of the Portuguese in their Asiatic, African, Oceanic, and American colonies. The Portuguese is as rich and concise as its sister languages; it has borrowed some words from the Arabic and the French; to the French it seems indebted for the soft sound of *g*, and for the nasal syllables; it is sonorous, soft, and unimpeded by the aspirates and gutturals of the Spanish; but the frequency of hiatus, and of the modern nasal *ao*, equisonant with the French *am* or *an*, injure the harmony of the language. Its origin, like that of the Spanish, is dated in the eleventh century; and it had attained its maturity in the sixteenth. The Portuguese literature, which Camoens illustrated with one of the finest epics in existence, is as varied and rich as the Spanish, though less known. It revived in the memorable reign of Joseph. The language may be said to exhibit no differences of dialect; there are only varieties: those which differ most from the written language are, the Minho, Algarve, and Azores varieties in Europe; the Brazilian in America; those of Congo and Mozambique in Africa; and of Goa and Macao in Asia. Some, however, regard as a dialect of the Portuguese, the jargon called *lingua geral*, spoken along the east and west coasts of Africa, especially in the region called by the French *Senegambia*, and in Guinea; also along the coasts of Ceylon and the Indian peninsula. In Africa, as well as in Asia, it presents the phenomenon offered by the *lingua Franca* in the Mediterranean, and attests the power formerly held by the Portuguese in those regions.

1343. *The Valaque or Wallachian*, spoken by the Rumanje or Roumouni, better known as Valaques, a people apparently descended from the ancient Roman colonists settled in Dacia and Thrace, and the Slavonic and other nations dwelling there. Its literature is very meagre. Among its numerous dialects the more remarkable are the Roumounic or Valaque proper, spoken in Wallachia, Moldavia, and Bessarabia; the Hungarian Valaque, the Macedo-Valaque, and the Kutzo-Valaque, spoken in various sub-dialects, in several parts of European Turkey, south of the Danube.

SUBJECT. 4.

1344. *The family of the Germanic languages* next claims our notice. Without entering into the history of the Germanic nations, which rivals in importance that of the Græco-Latin, we may class these different idioms, according to M. Malte-Brun's theory, in four branches; the *Teutonic*, the *Saxon* or *Cimbric*, the *Scandinavian* or *Normanno-Gothic*, and the *Anglo-Britannic*.

1345. *The Teutonic* branch, which comprises the idioms of the various ancient nations and tribes recognised as German by the Roman historians and writers; as the Bastarnæ, the Suevi, the Marcomanni, the Hermonduri, and the Franci, presents the following idioms:—

1346. *The ancient high German* (*alt hoch Deutsch*), formerly spoken in different dialects throughout South Germany, Switzerland, Alsace, Hesse, Thuringia, Wetteravia, and a great part of the countries once subjected to the Franks. It has been extinct for several centuries: its three principal dialects were, the Francic, and the Alemannic, which are of contemporary origin, and contain the most ancient productions of that language, and the *Middle High German*, which succeeded them. The *Francic* or *Tudesque* was the language of the Franks: it was spoken at the court of the Merovingian and Carlovingian sovereigns, until Charles the Bold; after whose reign it gave way to the old French in France, but continued to be the court language in Germany until the times of the Hohenstaufen. The *Middle High German*, according to the erudite Dr. Grimm, is the language in which were composed the numerous works of the Suabian, Bavarian, Austrian, and Swiss writers, and several other authors in Middle and Lower Germany, from the eleventh to the fifteenth centuries. Its finest productions are dated in the period of the Hohenstaufen, from 1136 to 1254, called also the *Minnesänger*, the *trouveurs* and *troubadours* of Germany. The *Nibelungen-lied*, the finest epic in this language, is supposed by Winter to have been composed in 1290, by Conrad of Würtzburg.

1347. *The German*, called also *neu hoch Deutsch*, in which distinction must be made between the written and the spoken language. The latter is divided into a great number of very different dialects, subdivided into several sub-dialects and varieties. The written language is nowhere spoken by the people; it was formed at the period when Luther, rejecting the *Middle High* and the *Middle Low German*, adopted in preference the dialect of Misnia or Meissen, which had begun to be written much later. This Misnian dialect, ably employed

by that great man and his numerous followers, soon became, as the language of books and of good society, common to all well-educated Germans, and also ranked as the learned language of the north and great part of the east of Europe. The literature of Germany, in regard to the quality of its productions, rivals those of France and England, and surpasses them in abundance. The German is the richest in words of any language in Europe; and this distinction it owes to the great number of its monosyllabic roots, with which it creates new terms *ad infinitum*, by derivation and composition. Its principal dialects are, the Swiss; the Rhenish; the Danubian, with its four sub-dialects, the Bavarian, the Tyrolean, Austrian, and Bohemo-Hungaro-Silesian; and the Franconian, or Mittel-Deutsch. To these, on the authority of Adelung, we may add two others, remarkable for the strange admixture of words totally foreign; these are, the *German Jewish*; and the *Rothwelsh*, spoken by the *Jenisch* or *Jauner*, who are generally reported to be thieves and vagabonds. It contains a multitude of terms and expressions quite different from German.

1348. *The Saxon, or Cimbric*, which comprises the idioms anciently spoken by the *Cimbri*; also by the *Angli*, who, with the *Jutes* and *Saxons*, afterwards made so great a figure in northern history; the *Bructeri* and *Chauci*, the *Menapi*, the *Tungri*, the *Batavi*, the *Frison*es, and other nations of less note, the ancient *Saxons*, and probably the *Longobardi*. This branch includes the four following idioms:—

1349. *The ancient low German (alt nieder Deutsch)*, called also the ancient *Saxon*, after the people who spoke it. This language, now extinct, was current throughout Lower Germany and the Netherlands, except in the countries occupied by the *Frison*es and the *Angli*. About the commencement of the seventeenth century it wholly ceased to be written. Its principal dialects are, the *Saxon proper*, or idiom of Lower Saxony; the *Eastern Saxon*, spoken in various subdialects in Prussia, and the *Westphalian*, or Western Saxon.

1350. *The Frisic*, formerly spoken along the coast, from the Rhine to the Elbe, by the *Frison*es, and their allies the *Chauci*, the ancestors of the present *Frisians*, who are now far from numerous, and speak a language very different from the ancient *Frisic*, being mixed with other idioms. Its three principal dialects are, the *Batavian Frisic*, the *Westphalian Frisic*, and the *North Frisic*, or *Cimbric*.

1351. *The Netherlandish, or modern Batavian*, has two principal dialects, the *Flemish*, and the *Hollandish*, or, as it is commonly called in this country, the *Dutch*. The *Flemish* is spoken in the southern provinces of the kingdom of the Netherlands, excepting those where German and French are spoken. It was the written and oral language of the seventeen provinces once subject to the Counts of Burgundy. After their extinction, and under the Spanish rule, the *Flemish* idiom gradually gave way in the north to the *Dutch*, in the south to the French language. *The Dutch* is spoken in different varieties in the seven provinces of the North, and in some bordering districts of the South: with certain changes and admixtures it is also spoken, or at least understood, in the various settlements founded by the Dutch of Africa, Oceania, and America, and in several places in Ceylon, India, and the peninsula of Malacca; in South Africa; at the Cape of Hope; and on the American continent in Guiana. Some thousands of Dutch settlers also in New York, Pennsylvania, and New Jersey, retain their native language. It was only in the sixteenth century that this vulgar idiom of the province of Holland, in some degree polished and improved, became the national language of the Dutch. It is a mixture of ancient *Francic*, *Frisic*, and low German.

1352. *The Scandinavian, or Normanno-Gothic*, comprises the idioms formerly spoken by the *Jutes*, the *Goths* or *Gutæ*, and other less considerable nations of pure Gothic race. There are five different idioms in this branch:—

1353. *The Mæso-Gothic*, formerly spoken by the *Goths* established in *Mæsia*. According to Dr. Grimm, this is the richest of the Germanic languages in grammatical forms: it has not less than fifteen declensions, with 120 cases, and sixteen conjugations. The *Mæso-Gothic* has been dead many centuries. Its most ancient productions are, the famous *Codex Argenteus* of Upsal; and other fragments of the translation of the Bible, made between the years 360 and 380, by Bishop *Ulphilas*. The *Mæso-Goths* appear to have been the first to embrace Christianity of all those nations who overthrew the Roman empire. According to M. Bopp, the *Mæso-Gothic* resembles the Sanskrit more than the Sanskrit resembles the Bengalee.

1354. *The Normannic*, called by Dr. Grimm the *Alt-Nordish*. It is the language of the *Edda*, of the *Voluspa*, and other poems of uncertain date, and was generally spoken throughout Scandinavia in the eighth, ninth, and tenth centuries.

1355. *The Norwegian, ancient Norwegian, Norræna tunga*, not to be confounded with the modern Norwegian or Norsk, which is only a dialect of the Danish. Its principal dialects are, the *Icelandic*, the *Norwegian proper*, the *Dalska*, or Western Dalecarlian, the *Jämtlandish*, and the *Norse*, spoken in the Shetland Isles.

1356. *The Swedish (Svenski)*, spoken by the Swedes throughout the greater part of the Swedish monarchy; also in the principal towns of Finland and the isle of Runoe, in the Russian empire. It has two principal dialects, the *Swedish*, and the modern Gothic, subdivided into several sub-dialects and varieties.

1357. *The Danish*, spoken by the Danes in Denmark, and in their Asiatic, African, and American settlements; also by the higher classes in the Ferøe Isles, and in Iceland. It has two principal dialects, each having several sub-dialects and varieties: the *Danish proper*, which includes the insular Danish, the ancient sub-dialect of Bornholm, the modern Norwegian, and the idiom of Scania. The *Jutlandish*, or modern Jutic, including the Normanno-Jutic, the Dano-Jutic, and the Anglo-Jutic.

1358. *The Anglo-Britannic* (not to be confounded with the *British*, which is *Welsh*,) comprises only two idioms.

1359. *The Anglo-Saxon*, formed by a mixture of the idioms spoken by the Angli, the Saxons, and the Jutes, who, invited by the Britons against the Picts, finally took possession of the country, where their language was successively preserved in three dialects, until the eighth century. During the invasions and temporary ascendancy of the Danes, it was so modified as to become *Dano-Saxon*, or rather this may be called a dialect of the Anglo-Saxon. For several centuries this language has been totally dead; but from its literary importance it is studied in the English universities, and has of late attracted much attention.

1360. *The English*, spoken in England, in the east and south-east of Scotland, in part of Ireland and of Wales; in the Shetland Isles, in the isles of Jersey and Guernsey, in the British colonies of Asia, Oceania, Africa, and America. It is the national language of the United States of America. It is also cultivated and spoken by a great number of persons of different nations in all parts of the world on account of its literary, political, and commercial importance: the two latter considerations render it very current in the kingdom of Hanover, in the Ionian Isles and Malta, in Portugal and Brazil, and in the republic of Hayti. The English language is a mixture of the Anglo-Saxon and the Neustrian French or Franco-Norman, with some Celtic words, and a few of ancient British origin. It has imported largely from the Greek and Latin, as knowledge and culture advanced in the nation. If the number of words in the language be taken at thirty-eight thousand, those of Saxon or northern origin will be found limited to about eight thousand, the rest being principally Greek and Latin derivatives. Copious and energetic, the English language is the simplest and most monosyllabic of all European idioms; and it is that also of which the pronunciation differs most from the orthography. It did not become the language of the state until the reign of Edward III., since which time it has rapidly improved. Towards the commencement of the seventeenth century may be dated its regular developement, and in the beginning of the eighteenth it took its fixed and invariable form. The English language occupies one of the most eminent places in European literature; it is comparable with any of them in elegance, and perhaps, surpasses them all in energy. It is no less graceful than concise; its poetry is at once manly and harmonious; and, like that of the cognate languages of the north, is admirably adapted to depict the sublimities of nature and portray the stronger passions: as the language of political and parliamentary eloquence, *it is without a rival*. Of the number of its dialects it might be difficult to speak with precision: foreign philologists distinguish four as the principal: — the *English proper*; the *Northumbrian English*, called also *Dano-English* from the great number of Danish words retained in it, and spoken in various sub-dialects in Yorkshire, Lancashire, Cumberland, and Westmoreland: the *Scottish or Anglo-Scandinavian*, including the *Lowland Scottish*, with the Border language; and lastly the *Ultra-European English*, prevalent in all the English colonies and in the American United States. It has been observed that the English language is spoken by the *greatest number* of the inhabitants of the New World.

SUBJECT. 5.

1361. *The family of the Slavonic languages* is widely diffused. From the neighbourhood of Udina in Italy, from Sillian in the Tyrol, and from the centre of Germany to the remotest extremities of Europe and of Asia, and even to the north-west coast of America, are nations of Slavonic origin to be found; the tract of country over which they hold sway amounting to about a sixth part of the habitable surface of the globe. These nations exhibit almost all the varieties of the human race, both physical and moral, if not from the most exalted, at least to the most degraded.

1362. *The Slavonic languages*, so far as is at present known, may be regarded as forming three branches: — 1. The Russo-Illyrian. 2. The Bohemo-Polish. 3. The Wendo-Lithuanian.

1363. (1.) *The RUSSO-ILLYRIAN* is so called from its chief people, the Russians, and from the general appellation Illyrian given to most of the nations who speak Servian or Croate. The languages comprised in this branch are: —

1364. *The Slavonic, Servian, Serbe, or Illyrian*, called also by some authors *Rutena*, spoken in different dialects by the more southern Slavi, generally denominated Illyrians. They dwell in the Austrian and Ottoman empires, excepting a small number, settled as colonists in south Russia. The dialects differing most from each other, and from the ancient Slavonic are, the *Servian or Serblin*, with various sub-dialects; the *Italiano-Slavonic*, spoken on the coast of Dalmatia; the *Uskoike*, spoken by the wandering tribes in Servia, Bosnia, Dal-

matia, Croatia, Maritime Hungary, and Carniola. It is mixed with many Turkish words. Lastly, the *Bulgarian*, spoken in Bulgaria, in the Ottoman empire.

1365. *The Russian, Ruski, or modern Russian*, spoken throughout the Russian empire by the Russians, who are the ruling nation; also spoken in a great part of Gallicia and part of Hungary in the Austrian empire. Since the reign of the Czar Peter, when the Slavvenski was abandoned for the Ruski, it became the language of literature and of business throughout Russia. It has the following dialects, which differ little from each other, the *Veliki-Ruski*, or Russian of Great Russia; the *Malo-Ruski*, or Russian of Little Russia; the *Suzdalian*; the *Olonetzian*, and the *Rusniac*.

1366. *The Croate*, spoken by the Croates or Khorbates, who delight to call it the *Illyrian*.

1367. *The Wende or Winde*, spoken by several Slavonic nations subject to the Austrian empire, and known by different names in the countries they inhabit. In the Wende appear to be distinguished three principal dialects, the Carniolan, the Carinthian, and the Styrian.

1368. (2.) *The BOHEMO-POLISH*, named from its two principal nations, the Bohemians and the Poles. The languages belonging to this branch are, the *Bohemian* or *Chekhe*, including the Bohemian proper and certain idioms, bearing the character of principal dialects, and spoken in the Austrian empire.

1369. *The Bohemian proper*, or *Chekhe*, is spoken in several very different sub-dialects by the Chekhes or Czecks, better known by the appellation of Bohemians. The dialect of Prague is the most elegant and pure. The others are the *Slowac*, the *Hannac*, the *Straniac*, the *Passekarsk*, the *Sallashac*, and the *Szotac*.

1370. *The Polish* is spoken by the Poles, called, in the middle ages, Lechen or Liachy. They form more than three fourths of the population of the present Russian kingdom of Poland, almost the whole population of the republic of Cracow, and of the western part of Gallicia, in the empire of Austria. They also form three fourths of the population of the grand duchy of Posen, two thirds of that of West Prussia, and part of that of Silesia. The Polish is also the national language of the nobility and part of the commonalty in all the countries formerly belonging to the kingdom of Poland; and is spoken by thousands of colonists in Russia. Its principal dialects are those of Great Poland, of Little Poland, of West Prussia, of Mazovia, of Polish Silesia, of the Germalys or highlanders, belonging to part of the Crapacks in Gallicia. The preference given in Poland to the Latin, long retarded the progress of this national language.

1371. *The Serbe or Sorabe*, spoken until the fourteenth century by the Serbes or Sserske. It has two dialects; the Upper Lusatian, and the Lower Lusatian.

1372. (3.) *The WENDO-LITHUANIAN*, called also the *Germano-Slavonic*. This branch comprises the following idioms:—

1373. *The Wend*, spoken until the fourteenth century in different dialects throughout the north of Germany, from Holstein to Pomerania, by various nations, as the *Wagrians*, the *Polabes*, the *Wilzians*, the *Obotrites*, the *Rugians*, and the *Pomeranians*. Since the fourteenth century it has been extinct, with the exception of the *Linonish*, improperly called the *Pola-bish* dialect, which subsisted in some districts until the latter half of the eighteenth.

1374. *The Prucze or ancient Prussian*, formerly spoken in eleven very different dialects, by the tribes forming the powerful nation of the Pruczi, dwelling between the Vistula and the Pregel. It is almost entirely extinct.

1375. *The Lithuanian or Littauish*, formerly spoken by those powerful nations the Lithuanians and Kriwitschi, and now current only among the common people; as the higher classes speak Polish, with Russian or German, according to their different countries. Its principal dialects have been thus classed:—The *Lithuanian proper*, the *Samogitian*, the *Kriwitsh*, and the *Prusso-Lithuanian*.

1376. *The Lette, Lettwa, Lettonian, or Lettish*, spoken by the Letts or Lettons, forming the bulk of the population in the government of Mittau, a large part of that of Riga, a small portion of that of Witepsk in Russia, and of the province of East Prussia. It has five principal dialects, subdivided into a multitude of very different sub-dialects. The former, according to Mr. Watson, are, the *Lette proper*; the *Semgallian* or *Semgallish*; the *Letto-Livonian* or *Lieflandish*; the *Seelian*, spoken by the Seeles in Courland: the *Wende*, by the Wendes, in the north-east of that duchy, particularly in the neighbourhood of Windau. This language abounds with German phrases and expressions.

1377. *The Slavonic nations employ five different alphabets*:—1. The *Cyrillian*, invented by St. Cyril in 865, called also the *Servian* or *Ruthenian*. 2. The *Glagolitic, Slavonic, Krukowitza*, or *Divinca*, called also that of St. Jerome. 3. The *Russian alphabet* of the Czar Peter, which is the *Cyrillian* modified by that emperor: it has thirty-five letters, and is in use throughout the Russian empire. 4. The *Sorabes, Bohemians, and Slavo-Silesians* use the *German alphabet* or character. 5. The other Slavonic nations, as the Poles, Lithuanians, Lettes, and Wendes, use the *Latin or Roman letters*. To these five alphabets may be added the *Runic Wend*, the *Greek alphabet*, adopted, according to Karamsin, by those Slavi who, in the eighth century, settled in Peloponnesus; and, lastly, the *Bulgarian*, imitated from the *Glagolitic*, and used by the Bulgarians.

SUBJECT. 6.

1378. *The family of the Uralian languages*, also called the Finnish or Chudic, completes the ethnographic division of Europe.

1379. *From the north-west coast of Norway to the long chain of the Urals*, and beyond those mountains to near the Yeniseï in the centre of Siberia, in another direction from the Leitha to the Seret, and from the Krapacks to the Danube, nations of Uralian race live among other nations, and retain the manners, habits, and language of their forefathers. In marking the gradations among the people composing this family, we may consider the Hungarians and the Ostiaks as exhibiting the two extremes in a moral as well as physical respect, notwithstanding the great affinity of their respective languages.

1380. *The Uralian family includes four branches*, according to M. Klaproth; but some languages not included in them may be separately considered as a fifth.

1381. *The Finnish, or Germanised Finnish branch*, includes the four following languages:—

1382. (1.) *The Finnish proper, or Suomenkieli*, spoken by the Suomi, better known as the Fins or Finlanders. Its principal dialects are, the Finlandish, the Tawastian, the Carelian or Kyriala, the Olonetzian, and the Watailaiset.

1383. *The Esthonian* spoken by the Esthonians or Esthen, whose ancestors were formidable pirates, and who now form the most numerous part of the population of the government of Reval, and of the circles of Pernau and Dorpat in that of Riga. Its two principal dialects are that of Reval and that of Dorpat.

1384. *The Lapponian*, spoken by the Sames, better known as the Lappons or Laplanders, inhabiting the northern extremity of Europe, partly under the monarchy of the Swedes, and partly under the Russian empire. This language, which is said to have more affinity with the Hungarian than with the Finnish, has a great number of very different dialects, which have been classed under the *Lappo-Norwegian*, the *Lappo-Swedish* (western and eastern), the *Lappo-Russ*, spoken in the circle of Kola, in the government of Archangel. Through the beneficent care of the Swedish government, at the close of the last and the beginning of the present century, the Laplanders have been reclaimed from idolatry, and have begun to enjoy the blessings of Christianity and civilisation.

1385. *The Livonian*, spoken formerly by the *Lives* or *Liven*, who gradually abandoned this idiom for the Lettish, in consequence of which it is become nearly extinct.

1386. (2.) *The Wolgaic branch* includes the languages spoken along the Wolga and its tributaries. They have a strong admixture of Turkish, and may rank under two classes, the Cheremisse and the Mordvine, including as dialects the Mokshau and the Ersan.

1387. (3.) *The Permian branch* includes two languages, the *Permian proper*, spoken by the Komi or Permians, and the Syrenes or Syranes; and the *Wotieque*, spoken by the Udi or Wotiaks scattered among the governments of Wiatka, Oremburg, and Kasan. They are all Christians, and, though exceedingly filthy, the most industrious people of Uralian race in the Russian empire, except the Fins and perhaps the Esthonians.

1388. (4.) *The Hungarian branch* includes the following languages:—

1389. *The Hungarian or Magyar*, spoken by the Magyars and Hungarians. They form about a third of the population of Hungary, and almost a fourth of that of Transylvania; several thousands also of this people are settled in the Boukowine in Gallicia, and about forty thousand in Moldavia, under the Turkish sway. The Hungarian, according to M. Czaplowicz, has four principal dialects:—1. The *Paloczen*. 2. The dialect of the *Magyars beyond the Danube*. 3. That of the *Magyars of the Theiss*; and 4. That of the *Szekler*, living in Transylvania, in the Boukowine, and in Moldavia. The Hungarian language is very harmonious; and is mixed with many foreign words, especially Slavonic, German, and Latin.

1390. *The Wogoule*, spoken by the Mansi or Manskum, more known as the Woguls, and called Wogoulitshe by the Russians. They are almost all Christians, and live principally as hunters and fishermen, scattered over the government of Saratow, in the high valleys of the Ural, in that of Perm, and in that of Tobolsk, between Kourjan and Beresow. Klaproth distinguishes in it four dialects, that of Chiosow, those of Werchoturja, and Cherdin, and that of Beresow in the government of Tobolsk.

1391. *The Ostiak, or Obi-Ostiak*, which is not to be confounded with the Yeniseï family. The *As-jachs* or *Ostiaks* of the Obi, who speak this language, are mostly Christians; some are still idolaters. The principal dialects are those of *Beresow*, *Lumpokol*, *Wass-i-gun*, and *Narym*. Under the branch still uncertain are ranked the *Hunniac*, the *Awar*, the *Bulgarian*, and the *Chazar*.

CHAP. II.

ENGLAND.

1392. *The British islands* may reasonably claim priority of notice in a general survey of Europe. Independently of their peculiar interest to us as natives, they derive a fair title to this distinction from their pre-eminence in arts, in arms, in all that constitutes the greatness and prosperity of a state. This insular empire, placed nearly in the north-western angle of Europe, commands peculiar advantages in its relations with that continent, no less for natural strength in war, than as an emporium of commerce in peace: on its southern side, it is almost in contact with France, Holland, and Germany, for ages the most enlightened and flourishing countries of the civilised world; on the east, a wide expanse of sea separates it from the bleak region of Scandinavia; on the west, it overlooks the Atlantic Ocean, whose limit in another hemisphere is the coast of America; while, in the extreme north, it may be

almost said to face the unexplored expanse of the Polar Sea. Exclusive of the northern insular appendages, it may be considered as situated between the fiftieth and fifty-ninth degrees of north latitude, and between the second degree of east and the tenth of west longitude. It is geographically divided into two islands of unequal magnitude, Great Britain and Ireland; the latter being inferior to the sister isle in length by more than half, though nearly equal in average breadth. Britain, again, is divided into two unequal parts: England, which, including Wales, contains 57,960 British square miles; and Scotland, which contains 30,500, and the three, though now united into one kingdom, under one legislature, respectively exhibit peculiarities which characterise them as distinct countries. It will, therefore, be requisite to describe each separately, commencing with England, which cannot by the strongest national partialities be denied to be foremost in wealth, population, and power. Being also the seat of empire and legislation, the chapter which treats of England will afford the proper place for many details, particularly of a political nature, which are alike applicable to her with the two sister countries.

SECT. I. *General Outline and Aspect.*

1393. *England is bounded on the south by the English Channel, interposed between its coast and that of France; on the east by the German Sea, on the north by Scotland, from which it is separated by the Tweed, the Cheviot hills, and the Frith of Solway; on the west by the Irish Sea and St. George's Channel: the promontory of the Land's-End, forming its south-western extremity, faces the vast expanse of the Atlantic.*

1394. *The greatest dimension of England is from south to north, between the Lizard Point, 49° 58' N., and Berwick on Tweed, 55° 45' N.; making five degrees and three quarters, or four hundred miles, in length. The points of extreme breadth are the Land's-End (fig. 104.), in 5° 41' W., and Lowestoffe, in 1° 44' E., forming a space which may be estimated in this latitude at 280 miles. There is no point, however, where a line of this extent can be carried across the island, and the northern part does not on an average exceed one hundred miles in breadth. The area, as already stated, in a late parliamentary report, is computed at 57,960 square miles.*

all the varieties of mountain scenery : in Cumberland, encircling little plains filled with beautiful lakes ; in Wales, enclosing narrow valleys through which the rapid mountain stream dashes ; in Derbyshire, presenting rocky scenery in every picturesque and fantastic shape ; while in Devonshire low broad steeps overshadow wide and beautiful vales.

1396. *The rivers of England* cannot be expected to rival in magnitude those mighty streams which roll through continents, and mark the boundaries of empires. As, with one exception, the most important of them traverse the breadth of the kingdom, rising among the western hills, and flowing toward the German Ocean, they do not attain that length of course which the extent of its territory in another direction would have admitted. The Thames, the pride of England, would almost be disdained by the Danube as a tributary. Though thus deficient, however, in magnitude, the rivers of England are numerous, commodious, and valuable ; flowing through broad vales and wide-spreading plains.

1397. *The Thames*, though not the longest, deserves to be ranked as the first of British rivers. It originates from a number of rivulets on the borders of Wilts and Gloucestershire, which, uniting at Cricklade, form a stream which is about nine feet broad in summer, and is called the Thame. At Lechdale, being joined by the Lech and the Coln, it becomes navigable for barges of ninety tons. Near the classic haunts of Oxford it receives the Charwell and the Isis, assuming on its junction with the latter river the compound name of Tamesis, which has been abbreviated into Thames. After a course almost southward to Reading, it winds northward through the wooded vale of Henley and Maidenhead, and thence by the castellated heights of Windsor. Its onward course to London is by Chertsey, Hampton, Twickenham, and Richmond, among the magnificent woods and palaces of this paradise of England. Near Teddington its current is slightly acted upon by the extreme ebb and flow of the tide, which rises higher in this than in any other river of Europe. Before reaching London, it attains a magnitude corresponding with the capital of the empire, which it divides into two unequal parts, having on its northern bank the cities of London and Westminster, and on its southern the borough of Southwark. Below London bridge it is navigable for vessels of large burthen ; its ample channel, and the spacious adjoining docks connected with it, are there constantly filled with forests of masts, and seem to contain, as it were, the wealth of the world. It winds its way to the ocean through a country by no means remarkable for picturesque scenery, and presenting few objects of interest, except the vast naval establishments situated on the south bank of the river. Woolwich claims particular attention, not only on account of the royal dockyard, and the national depôt of artillery, but for its military academy, which ranks as the first in the empire. The great estuary of the Medway opening into the river from Kent affords commodious sites for the naval stations of Chatham and Sheerness. The entire course of the Thames is about 220 miles.

1398. *The Trent*, though superior in length, cannot rival the imperial magnificence of the Thames ; yet the national advantages derived from it are of a very high order. Together with its tributary, the northern Ouse, it traverses the whole midland territory of England, and several of its principal manufacturing districts, to which it affords a communication with the eastern, and by canals with the western, ocean. It springs from several sources among the low Staffordshire hills, and does not attain any considerable magnitude till it reaches the thriving town of Burton, where it becomes navigable for vessels of moderate size. For some extent it rolls its silver stream through fertile meadows, receiving the Dove and Derwent ; which, after dashing through the dark and rocky recesses of Derbyshire, have already subsided into peaceful streams. As the Trent passes Nottingham, and flows toward Newark, it penetrates a range of bolder scenery, through banks overhung with high swelling knolls and green feathered cliffs. At Gainsborough it becomes navigable for steam-boats, and other vessels of large burthen. After a farther course of about thirty miles, it flows into the Humber, already rendered a broad estuary by the Ouse, which has collected the principal streams of Yorkshire. The Ouse, formed originally by the confluence of the Aire and the Swale from the uplands of the North Riding, is subsequently augmented by the Wharfe. The Aire, with its tributaries the Calder and Don, enable it to communicate with all the great manufacturing towns of the West Riding, and the confluence of the Derwent from the East Riding renders it equal in magnitude to the Thames. The Ouse, with its branches, forms one of the most useful and least beautiful of English rivers. It winds a sluggish course through manufacturing districts and rich arable fields without any diversity of scenery. The Humber, formed by the junction of the Trent and Ouse, resembles an arm of the sea ; and its trade contributes mainly to the commercial prosperity of Hull.

1399. *The Severn* is not inferior in magnitude to any of the rivers already named, and is the only great stream which runs from north to south for a considerable part of its course ; too far to the westward, however, to attain the length which that direction might have given. Rising in Wales, near the foot of Plinlimmon, it flows first north, and then east through the vales of Montgomery ; receives another mountain stream, the Vyrnwy, and, after winding round the ancient town of Shrewsbury, directs its course to the southward, through some of

the richest and most beautiful plains of England, passing by the fine and ancient cities of Worcester, Tewkesbury, and Gloucester. In commercial importance it also ranks high, since it flows through Colebrook Dale, and other principal seats of the iron trade; while the tracts on its lower course have for ages been distinguished for the manufacture of fine woollens. Its navigation is not so easy, nor so free from obstruction, as that of the rivers already mentioned; but much has been done to obviate these disadvantages, and to connect the Severn by canals with the other great rivers. In approaching Bristol, it receives the Wye, which, rising in Wales from a source near its own, flows in a contrary direction through scenery which renders it the most picturesque of English rivers. The Severn then expands into the grand estuary of the Bristol Channel, equally important as a geographical feature, and as the haven of a commerce once second only to that of the metropolis, but now surpassed by that of the northern emporium, Liverpool.

1400. *The other rivers of England* are to be regarded as little more than local features. We cannot omit to mention the Eden, the beautiful river of Cumberland, which forms the Solway; the Mersey of Lancashire, which, with its tributary the Irwell, is important, not for its magnitude, but for the mass of commodities which it conveys from the great manufacturing districts to Liverpool, now the second commercial port in the kingdom; the southern Ouse, which, after a considerable course through the counties of Buckingham, Bedford, and Cambridge, combines with the Witham of Lincolnshire in forming that broad, shallow, marshy estuary called the Wash, through which is exported a considerable quantity of grain from the agricultural districts. Nor must we overlook the parallel streams of the Tyne and the Tees in the north of England, which rise in a rude mountain district; but, on reaching the plain, acquire a considerable volume of waters, and become the channels of extensive trade; the Tyne, in particular, which carries down the product of the vast coal mines of Newcastle. A system of canals, the most extensive that exists in any country, connects together all these rivers, and prodigiously augments their utility and value. The description, however, of these artificial means of communication may properly be reserved for another section.

1401. *The lakes of England* occur principally in the north-western counties of Cumberland and Westmoreland, which are specially denominated the country of the lakes. These, of which Windermere, the largest, is only twelve miles long and one broad, may be regarded as objects which have been raised to distinction by the taste of the age for picturesque beauty, rather than as geographical features of the country. Their number, which is considerable, entitles them to notice; and a detailed description of them will accompany that of the districts to which they belong.

SECT. II. *Natural Geography.*

1402. *This subject will be treated under the heads of Geology, Botany, and Zoology.*

SUBSECT. 1. *Geology of England.*

1403. *England is eminently distinguished from Scotland in geognostical constitution:* while in Scotland the prevailing formations belong to the *primitive* and *transition* classes, in England the deposits that most abound are the *secondary*, *tertiary*, and *alluvial*. Hence, also, it is that Scotland appears lofty and rugged, when contrasted with the hilly, flat, and low land of England.

1404. *Nearly all the accurate information in regard to the geology of England we owe to the zeal and activity of the members of the Geological Society of London; who, in following out the mode of investigation of the Wernerian school, and not neglecting the views and facts of Hutton, have, in a comparatively short period, brought together a very interesting series of facts. A short view of these will enable our readers to form a general conception of the geognostical structure of England. We shall consider the mineral formations in the following order:—* I. *Primitive and Transition.* II. *Secondary.* III. *Tertiary.* IV. *Alluvial.*

1405. I. *Primitive and Transition.* These rocks are principally confined to the more mountainous parts of England, and appear most abundantly, in the north, in Cumberland and some neighbouring counties; in the middle and west, in Wales; and on the south and south-west, in Cornwall and Devon.

1406. (1.) *Cumberland district.* This district is bounded to the west and the south by the Irish Sea and Morecombe Bay; towards the north it descends into the plain of the new red sandstone, within the basin of the Eden; and on the east it is bounded by the central carboniferous chain of the north. Within these limits there are the two sets of rocks, viz. Plutonian and Neptunian; the more central parts being Plutonian, and the others Neptunian. The order in which they occur, according to Otley and Sedgwick, is as follows:—

1. *Granite and Syenite.* They form the *geognostical axis* of all this region, and extend from the centre of the Skiddaw range to the neighbourhood of Egremont. There is a fine display of the granite in the bed of the Calden, near its source on the north-east side of Skiddaw, where it is intersected by veins of quartz, and contains, besides other minerals, molybdena, tungsten, wolfram, and phosphate of lime.

2. A series of crystalline slaty deposits, forming, for example, the centre of the Skiddaw region, viz. Skiddaw, Saddleback, Grisdale Peak, and Grasmere, with most of the Newlands mountains, and extending across Cromack lake, and by the foot of Ennerdale, as far as Denthill, is composed of gneiss, mica slate, hornblende slate, and chialstolite slate. These seem irregularly grouped: this irregularity is probably only apparent, because, when the primitive and transition rocks have been as well examined as the secondary, they also may be found to exhibit determinate arrangements. In some parts of Skiddaw and Saddleback the curious mineral named *chialstolite* occurs: veins of quartz and galena

occur in Thornthwaite, Newlands, Loweswater, and other places; a copper-mine was formerly worked in Newlands. The *salt springs* of Borrowdale issue from these rocks.

3. Deposit of clay slate.

4. An enormous formation of a green felspathose slate, intimately associated with porphyry, like that of Snowdonia in Wales, and the Needle's Eye in Scotland. The famous graphite or black-lead mine of Borrowdale is situated in the upper end of the valley of that name, where the graphite occurs in irregular veins associated with calc spar, brown spar, and quartz. The graphite is in nests in these veins, and the veins are contained in a Plutonian rock, viz. felspar porphyry, which is in some places amygdaloidal. Some nests of graphite have afforded 3000*l.* worth of that mineral.

5. Greywacke, with subordinate beds of limestone enclosing organic remains. A *gryphæa* and *turritella* occur near to Kirby-Lonsdale; a *pecten*, *plagiostoma*, *trigonia*, and *patella* near to Keswick. The species have not been determined. On the north side of the geognostical axis the Neptunian formations are repeated, with the exception of the greywacke series, which is probably buried under the old red sandstone and mountain limestone; and on this northern side, notwithstanding its less extensive developement, there is a group of mountains, almost entirely composed of *diallage rock*, and other minerals; of which, it is said, no trace occurs in the south. These occupy the place of the green felspar slate and porphyry series of No. 3. of Wales, afterwards to be noticed; and seem to be in the precise place of the serpentine of the Lizard in Cornwall. Further, there is on the west side of Cumberland another formation of granite and syenite, which underlies, traverses, and overlies the clay slate, No. 3., and is considered the great centre of elevation of the region. It never overlies, it is said, the mica slate, chialstolite slate, &c.; but is probably connected with veins of syenite, and other detached masses of crystalline rock, which do not belong to the ordinary rocks of superposition. Professor Sedgwick, in a paper read before the Geological Society, but not yet published, after describing, at great length, a range of transition limestone, which extends from Mellam in Cumberland to the neighbourhood of Wasdale Head in Westmoreland, nearly across the whole region we are now describing, states, that it is finally cut off by a protruding mass of granite, which he regards as newer than the limestone. On the phenomena exhibited in the Cumberland district the following conclusions have been founded: — 1st, Great cracks and fissures were formed at a very ancient period, diverging from the central regions, and intersecting the line of bearing of the strata. All the great valleys in the district are scooped out in the prolongation of these breaks: which were, in all cases, accompanied with internal movements; the present position of the systems of strata on the opposite sides of a transverse valley sometimes indicating a relative lateral movement of more than a mile in extent. These singular changes of position are referred partly to a true lateral shift, and partly to a subsidence. Reasoning from analogy, Professor Sedgwick concludes, that all the great diverging valleys of the Lake mountains took their origin in fissures, probably formed during the period of the protrusion of the central granite and syenite. 2dly, The upper and lower systems of Neptunian strata, the slaty crystalline rocks, and the greywacke, are often violently contorted; while the central system, or clay slate, though traversed by numerous rents, hardly ever exhibits the indications of any flexures. This is explained by the presence of enormous unbending masses of compact felspar porphyry, &c., which are so intimately associated with the middle division of the slate, that the formations cannot be separated. The appearance is explained by referring the felspathic rocks to some modification of sub-marine volcanic action; by supposing that igneous and aqueous causes acted together, and that the operations were many times repeated. 3dly, The mean line of bearing of the different sets of Neptunian strata appears to be N. E. by E., and S. W. by W. This makes them, one after the other, to abut against the carboniferous zone where they meet with it: from which it follows that they must also be unconformable to it. Professor Sedgwick concludes from the whole evidence, that the central Lake mountains were placed in their present position, not by a long continued, but by a sudden movement of elevation, before or during the period of the old red sandstone.

1407. (2.) *Wales, including the Isle of Anglesea.* The Neptunian and Plutonian rocks in this extensive district are arranged as follows: — 1st, *Granite* rising among the clay slate strata in the Isle of Anglesea. 2dly, A group of slaty rocks consisting of mica slate, chlorite slate, and quartz rock. These appear upheaved by the subjacent granite. They occur in the Isle of Anglesea. In this island are the great Mona marble and Paris copper mines, in which the ore is common copper pyrites. The Mona marble, a beautiful compound of marble and serpentine, occurs among these rocks. 3dly, A great group, differing from the ordinary characters of the Welsh mountains, in containing a very large proportion of felspathose rocks and porphyries. Of these the grand district of Snowdonia are probably the lowest portion. Some of the slates of the Snowdon range contain organic remains, principally of shells, some of which appear referrible to the genus *Producta*. 4thly, A vast deposit of clay slate. 5thly, Greywacke, which forms the uppermost or newest member of the great series of deposits. Connected with these series are great beds of

limestone. Fossil organic remains are met with in this series, and much more abundantly than in the deeper-seated slates. *Corals* of various kinds, *crinoid* animals, shells, and *crustacea* occur among these rocks, in a fossil state. Of *fish*, the remains of bones, teeth, and the defensive fin-bones named *ichthyodorulites*, are met with. The most curious of these remains, the *Crustacea*, abound in vast numbers in some parts of Wales: as the *Asaphus Debuchii*. In the lists of organic remains of these slates we find extinct genera, and genera that still exist: and, judging from the nature of the remains, we infer that some of the animals were inhabitants of deep, others of shallow, seas. The organic remains in greywacke rocks are rare, and therefore form a very small proportion to the extent of the rock. We do not remember of any fossil plants having been met with in the slates of Wales; although, from their occurrence in similar slates in other countries, it is probable they will also be found there.

1408. (3.) *Cornwall and Devon*. In this district of England the rocks of the primitive class are arranged in the following order: — 1st, *Granite*. There are four great projecting masses of granite rising through the bounding slaty strata: they send arms or veins among the Neptunian strata, and have upraised and variously modified them. The granite is traversed by contemporaneous veins of granite, and also encloses contemporaneous masses and veins of a compound of quartz and schorl, named *schorl-rock*. It is also traversed by veins of porphyry, called *elvan*. 2dly, Resting upon, or adjacent to, the granite there is a vast deposit of clay slate, named, in the county, *killas*. It abounds in ores, hence, is sometimes named *metalliferous slate*. Where in the vicinity of granite, there is interposed gneiss or mica slate, or both: and in many parts it contains subordinate beds of greenstone, felspathose slate, &c. 3dly, Apparently above the preceding slates there occurs, in two places, a formation of *serpentine*, which, in the Lizard, contains *diallage rock*, *talc slate*, *hornblende slate*, and *mica slate*, and appears to occur below the greywacke. 4thly, *Greywacke*. This, which appears to form a great mass, is the uppermost and newest member of the stratified series. It contains considerable beds of limestone, including various organic remains.

1409. *Mines in Cornwall and Devon*. Cornwall and Devonshire present three principal mining districts. 1. The part of Cornwall situated in the vicinity and to the southward of Truro, the neighbourhood of St. Austle, and the neighbourhood of Tavistock. The first of these districts is the most important of the three, from the number and richness of its mines, in which copper, tin, and lead are obtained. The ores of copper, which are principally copper pyrites and grey copper, form regular veins, having a direction nearly from E. to W. in the rock named *killas*; and sometimes in the granite which projects amongst the slaty strata. The tin occurs principally in veins, which, like the preceding, traverse the *killas* and granite. They have also, very often, a direction nearly from E. to W.; they have a different inclination from that of the copper veins, which intersect and interrupt them, and which are, consequently, newer. The tin also occurs in contemporaneous masses and veins, and disseminated through the granite. Some veins afford, at the same time, copper and tin; but most of them produce only one of these metals in any quantity. There are also in Cornwall *cross veins*, that intersect the veins both of copper and tin; these contain argentiferous galena, native silver, and ores of silver. Near to Tavistock there are veins of copper, tin, and lead. Mines of antimony occur at Huel Boys in Devonshire, and at Saltash in Cornwall. The tin and copper ores of Cornwall are accompanied with arsenical pyrites, which is turned to profit by manufacturing oxide of arsenic from it.

1410. II. *Secondary Rocks*. The rocks of this class form the largest portion of the surface of England, and the districts composed of them are generally flat or hilly; never assuming the mountainous character, unless where the old red sandstone or mountain limestone appears. We shall now describe the different formations in the order in which they occur, beginning with the deeper seated or oldest (the old red sandstone), and finish our view with an account of the newest or chalk.

1411. (1.) *Old red sandstone*. This sandstone, which is distinguished from those newer in the series by its greater hardness and red colour, occurs in greatest abundance in Herefordshire and Brecknockshire. Smaller portions occur in some neighbouring districts, and in the Cumberland district in the north. The Isle of Man and the Isle of Anglesea also afford deposits of this oldest member of the secondary class.

1412. (2.) *Mountain limestone, metalliferous limestone, or carboniferous limestone*. This rock in the regular succession, rests upon the old red sandstone. It is generally grey coloured; sometimes, however, it exhibits various tints when it is worked as an inferior kind of marble. Its fracture is compact, lustre glimmering, and opaque or translucent on the edges. Its structure is sometimes *oolitic*, as is the case in the vicinity of Bristol. Veins of calcareous spar frequently traverse it, and occasionally contribute to the beauty of the varieties used as marble. Sometimes remains of the encrinus are so abundant in it, that it is named *encrinural limestone*. Its name *carboniferous* is from its sometimes occurring along with coal, as that of *metalliferous* from its, in some districts, abounding in ores. It abounds in organic remains of various genera of *corals*, *radiaria*, and *shells*; also some genera of *crustacea* and *fishes*. These

bear a strong resemblance to the fossils of the transition limestone in the greywacke districts. Derbyshire, Northumberland, and Cumberland afford fine displays of this formation.

1413. *Mines in mountain limestone.* The mountain limestone forms several mountainous districts in England and Wales; in which there are three districts rich in lead mines. The *first* of these comprehends the upper parts of the valleys of the Tyne, the Wear, and the Tees, in the counties of Cumberland, Durham, and York. Its principal mines are situated near to the small town of Aldston Moor in Cumberland. The veins of sulphuret of lead or galena, which form the principal object of the works, traverse alternately beds of limestone and sandstone. They are very remarkable, from the circumstance that they suddenly become thinner and poorer on passing from the limestone into the sandstone; an arrangement probably connected with some electro-magnetic action. The lead obtained is poor in silver, and there is, we believe, only a single furnace in which that metal is extracted by cupellation. It also contains a copper mine some miles to the S. W. of Aldston Moor. The ore is common yellow copper pyrites, which is associated with galena in a vein of great extent, and which does not seem to belong to the same formation as the other veins in this county. The iron mines of Ulverston are in this district. The ore is red hematite, which traverses the limestone in the form of veins; some of which are said to be 30 yards wide. Near Whitehaven great masses of reniform hematite alternate with red beds of mountain limestone. The *second metalliferous district* is situated in the northern part of Derbyshire, and the contiguous parts of the neighbouring counties. The districts called Peak and Kingsfield are the richest in ore. The mines, although numerous, are not of great extent. The galena contains no silver, at least no silver is attempted to be extracted from it. The blende, associated with the lead, is worked as an ore, and zinc is obtained from it. A vein of copper pyrites occurs at Ecton in Staffordshire, on the borders of Derbyshire. The Derbyshire veins have been long famous on account of the beautiful minerals they produce, especially *fluor spars*, and also from the interruption which the metalliferous veins experience on meeting with trap rocks, called *toadstone*, which occurs alternately with the limestone. The *third metalliferous district* is situated in Flintshire and Denbighshire, which form the N. E. part of Wales. It is the most productive next to Aldston Moor. Besides lead, it furnishes also calamine or true ore of zinc. The mines are situated partly in the mountain limestone, partly in various rocks of older formation. To the S. W. of this district there are also lead mines in Shropshire: like the preceding they occur partly in mountain limestone and partly in older rocks. They yield a great annual return of lead. Some mines of galena and of calamine are mentioned as occurring in the Mendip hills to the south of Bristol; but they appear to be now abandoned. Many beautiful and interesting minerals are met with in these mines, as enumerated and described by mineralogists. Of the vein stones, quartz, in Cornwall, is the most abundant; while it is fluor spar and calcareous spar in Derbyshire; in Yorkshire heavy spar or sulphate of barytes; and in Cumberland, heavy spar and fluor spar.

1414. (3.) *Coal formation.* This, which is the most important of the secondary deposits, follows in the regular succession the mountain limestone, on which it therefore rests. The lower beds of this deposit sometimes alternate with the upper strata of the mountain limestone. The rocks of which it is composed are *shale*, *sandstone*, *clay ironstone*, *indurated clay*, and *coal*, alternating in various ways with each other. The shale, sandstones, ironstones, and clays contain numerous fossil remains of extinct species of plants, rarely of animals, the animal remains occurring principally in the limestone. No country of the same size in the world affords so much coal as England, and nowhere has its natural and economical history been so well examined as in this island. Messrs. Conybeare and Phillips arrange the different coal districts in the following manner:—

1. *Coal district north of Trent*, or grand Penine chain.—1. Northumberland and Durham. 2. North of Yorkshire. 3. South York, Nottingham, and Derby. 4. South of Derby. 5. North Stafford. 6. South Lancashire. 7. North Lancashire. 8. Cumberland and Whitehaven. 9. Foot of Crossfell.

2. *Central coal district.*—1. Ashby de la Zouch. 2. Warwickshire. 3. South Stafford or Dudley. 4. Indications near the Lickey hill, &c.

3. *Western coal district*, divided into, 1. *North Western* or *North Welsh*.—1. Isle of Anglesea. 2. Flintshire.

4. *Middle western* or *Shropshire*.—1. Plain of Shrewsbury. 2. Colebrook-dale. 3. The Clee hills and South Shropshire. 4. Near the Abberley hill.

5. *South Western*.—1. South Wales. 2. Forest of Dean. 3. South Gloucester and Somerset.

These different districts are accurately described in Conybeare and Phillips's *Geology of England and Wales*, to which valuable work we refer our readers, our limits not allowing us to enter into details.

1415. *Changes of the coal fields from the Bristol Channel to the Tweed.* The great coal fields in England experience a great change of structure in their range from the Bristol Channel to the valley of the Tweed: these changes we shall now enumerate, using the view

given by Sedgwick. In the various coal basins on the Bristol Channel, the limestone strata are developed only in the lower, and the coal beds in the upper, part of the series; and the two members are separated by nearly unproductive deposits of millstone-grit and shale. The arrangement in Derbyshire is nearly the same; there, however, the millstone-grit is more varied, and is of very great thickness, and subordinate to the great deposit of shale, and, here and there, very thick masses of a peculiar argillaceous sandstone, disposed in a tabular manner. On the re-appearance of the carboniferous limestone, at the base of the Yorkshire chain, we still find the same general analogies of structure; enormous deposits of limestone form the lowest part, and the coal fields the highest part of the whole series; and, as in the former instances, we also find the millstone-grit occupying an intermediate position. The millstone-grit, however, becomes a very complex deposit, with several subordinate beds of coal; and is separated from the great inferior calcareous group (the *scar* limestone), not merely by the great shale and shale-limestone, as in Derbyshire, but by a still more complex deposit, in some places not less than 1000 feet thick; in which five groups of limestone strata alternate with great masses of sandstone and shale, abound in impressions of coal plants, and three or four thin beds of good coal extensively worked for domestic use.

1416. *In the range of the carboniferous chain* from Stainmoor, through the ridge of Cross-fell to the confines of Northumberland, we have a repetition of the same general phenomena. On its eastern flanks, and superior to all its component groups, is the coal field of Durham. Under the coal field, we have, in a regular descending order, the millstone-grit, the alternations of limestone and coal measures nearly identical with those of the Yorkshire chain, and at the base of all is the great *scar* limestone. The *scar* limestone begins, however, to be subdivided by thick masses of sandstone and carbonaceous shale, of which we had hardly a trace in Yorkshire; and gradually passes into a complex deposit, not distinguishable from the next superior division of the series. Along with this gradual change is a great development of the inferior coal beds alternating with the limestone; some of which on the north-eastern skirts of Cumberland, are three or four feet in thickness, and are now worked for domestic use.

1417. *The alternating beds of sandstone and shale* expand more and more as we advance towards the north, at the expense of all the calcareous groups, which gradually thin off and cease to produce any impress on the features of the country. And thus it is, that the lowest portion of the whole carboniferous system, from Bewcastle Forest, along the skirts of the Cheviot Hills, to the valley of the Tweed, has hardly a single feature in common with the inferior part of the Yorkshire chain; but, on the contrary, has almost all the most ordinary external characters of a coal formation. Corresponding to this change, is also a gradual thickening of carbonaceous matter in some of the lower groups. Many coal works have been opened upon this line; and near the right bank of the Tweed (almost on a parallel with the great *scar* limestone) is a coal field, with five or six good seams, some of which are pretty extensively worked. The beds of sandstone, shale, and limestone, forming the base in the carboniferous system in the basin of the Tweed, are often deeply tinged with oxide of iron; and have been compared sometimes with the new, sometimes with the old, red sandstone: to the new red sandstone they have no relations; "and I would rather compare them," says Sedgwick, "especially as the old red sandstone of the north of England, seldom exist but as a conglomerate, and is seen in that form on the flanks of the Cheviot Hills, with the red beds of mountain limestone and sandstone, which, both in Cumberland and Lancashire, sometimes form the base of the whole carboniferous series."

1418. *These coal fields are traversed and variously deranged by great vaults*; interesting descriptions of which, particularly those in the northern fields, have been published by Messrs. Phillips and Sedgwick.

1419. *Economical importance of the coal formation.* The coal strata, or *metals* as they are sometimes called, are in some parts of England affected by Plutonian trap rocks, but in a very inferior degree to what takes place in Scotland. The principal trap rock is greenstone, which appears in the form of *overlying* masses, as at Clee Hill and at Dudley; in the form of intersecting tabular masses or *dikes* (veins), as in Northumberland and Durham. Sometimes the trap mass has been forced between the strata, when it has the character of a *bed*, or these bed-like masses may be some of the rocks of the coal formation softened and recrystallised *in situ* by heat from below. The great *whin sill* of Northumberland, and the toadstone beds of Derbyshire, are examples of these *trap beds*. The strata near the trap frequently appear changed, the clays hardened, the limestone rendered crystalline and magnesian, the coal charred, and the sandstone hardened, &c.; and these strata are either moved from their original position, or are unchanged. Although rather foreign to our subject, we may, as an illustration of the importance of the coal formation to England, mention the quantity of iron manufactured, and of coal consumed, in the carboniferous district of Wales.

1420. *The quantity of iron*, according to Mr. Forster, annually manufactured in Wales, has been calculated at 270,000 tons. Of this quantity a proportion of about three-fourths is made into bars, and one-fourth sold as pigs and castings. The quantity of coal required for

its manufacture on the average of the whole, including that used by engines, workmen, &c. will be about $5\frac{1}{2}$ tons for each ton of iron; the annual consumption of coal by the ironworks will, therefore, be about 1,500,000 tons. The quantity used in the smelting of copper ore imported into Wales from Cornwall, in the manufacture of tin-plate, forging of iron for various purposes, and for domestic uses, may be calculated at 350,000, which makes altogether the annual consumption in Wales, 1,850,000 tons. The annual quantity of iron manufactured in Great Britain is 690,000 tons. From this statement it will be observed that the quantity of iron smelted in Wales is upwards of one-third of the total quantity made in Great Britain. The manufacture of the Welsh iron is in the hands of a few extensive capitalists, and is carried on with great spirit and attention to improvement.

1421. (4.) *Magnesian limestone formation.* The upper part of the coal formation has sometimes a red colour with an arenaceous and conglomerated character, when it is named by the German miners *todliegende*. Above or resting upon it we have the magnesian limestone deposit. This deposit extends through Yorkshire and Durham. Its lower part is said to be separated from the coal formation by a deposit of sand and sandstone, with occasional red marl and gypsum. The magnesian limestone itself consists in its lower part of a *bituminous marl slate*, abounding in fossil fishes of the genus *Palæothrissum*; the middle and upper parts being a yellowish small granular or glimmering magnesian limestone. The organic character of this limestone approaches nearly to that of the mountain limestone already described. It contains *Productæ*, which, however, do not occur higher in the series; also *Spiriferæ*, a tribe found as high as the oolite.

1422. (5.) *Variegated or new red sandstone, with the red variegated marl deposit.* As the shell limestone is wanting in England, the variegated sandstone and the red and variegated marls come together, and may here, therefore, be viewed as one formation. They rest immediately upon the magnesian limestone, but of the two sets the marl appears in general to be the uppermost or newest. The sandstone is of a looser texture than that of the old red sandstone deposit, has a red or variegated colour, and the strata are generally horizontal. The marls are red or variegated in colour. In these sandstones and marls, beds and great masses or nodules of gypsum occur, as in Derbyshire, Staffordshire, &c. All the *salt mines* in England are situated in this deposit. At Northwich there is an extensive deposit of solid *rock salt*, forming two beds, together not less than 60 feet in thickness. These beds are supposed to form large insulated masses of this mineral, extending in length about a mile and a half, and in breadth about 1300 yards. The *salt works* at Droitwich in Worcestershire are also in this red marl deposit. Iron-sand and iserine are said to occur in this sandstone on the banks of the Mersey opposite Liverpool; and in other places sulphuret of copper, grey oxide of cobalt, and black oxide of manganese occur in the sandstone or its marls. It forms the surface of vast tracts extending with little interruption from the northern bank of the Tees in Durham to the southern coast of Devonshire. We find a tract in the great plain in the centre of England of about 80 miles in length and sixty in breadth, principally covered with this deposit; *several islands* of the *older rocks*, however, rising, in various places, through it. These are, 1st, the syenite, greenstone, and slate district of Charnwood forest in Leicestershire; 2dly, the coal district surrounding Ashby de la Zouch in the same county; connected with which are several patches of the carboniferous magnesian limestone, and a patch of millstone grit at Stanton-bridge on the Trent; 3dly, the coal-field of Warwickshire; 4thly, the coalfield in the south of Staffordshire, with the transition limestone on which it rests; 5thly, the lower and northern range of the Lickey hill, near Bromsgrove in Worcestershire, which exhibits strata, probably of transition quartz rock. Some *trap rocks* occur in this formation at Upton Pyne, a village five miles north of Exeter, and at other points near that town.

1423. (6.) *Lias and oolite formation.* This great formation in the regular succession rests upon the new red sandstones and marls. In no country are its various members so beautifully displayed as in England, where it was first accurately described by a *remarkable man*, William Smith, author of the first great geognostical map of England, and who, besides other merits, was, in England, one of the first to direct the attention of observers to fossil organic remains as a means of distinguishing beds of rock. Three great clay or marl deposits divide the series into three natural groups, as already explained at pages 223. and 224. In England it occupies a zone having nearly 30 miles in average breadth, extending across the island from Yorkshire on the north-east, to Devonshire on the south-west. It is eminently remarkable on account of the number and variety of fossil organic remains which it contains, and its wide distribution not only in England, but also in many other parts of the world. It is not likely that this vast limestone deposit was formed from organic remains. Whence then do we derive the calcareous matter? Werner remarked, that new matter appeared from time to time in the waters of the ocean — the calcareous carbonate appears to have been one of these matters, and may have come from the interior of the earth. It is in this formation, at Stonesfield, that the first or earliest remains of mammiferous animals were found. Crocodiles and many vast and strangely organised reptiles occur in this deposit, with a vast variety of shells, many *radiaria*, and also corals. Fishes are also met with

in a fossil state, but by no means so frequently as reptiles. Fossil plants of various tribes also occur, and thus add to the organic variety of this remarkable formation: they belong to the *Algæ*, *Equisetaceæ*, *Filices*, *Cycadeæ*, *Coniferæ*, and *Lilia*. Beds of coal, generally of an indifferent quality, occur in different parts of the country in this deposit.

1424. (7.) *Wealden clay and Purbeck stone*. This formation, which lies immediately upon the oolite, consists of limestones, sands, and clays abounding in fossil organic remains, principally of terrestrial and freshwater plants and animals, marine species being rare. In the lower part of this formation, in the neighbourhood of Weymouth, according to Buckland and De la Bèche, there is a bed of black earth, called the *dirt bed*, containing, in a silicified state, long prostrate trunks of coniferous trees, and stems of *Cycadeoideæ*. These trunks lie partly sunk into the deep black earth, like fallen trees on the surface of a peat bog, and partly covered by the incumbent Purbeck limestone. Many trunks of trees also remain erect, with their roots attached to the black soil in which they grew, and their upper part in the limestone; and show that the surface of the subjacent Portland stone was for some time dry land, and covered with a forest; and probably in a climate such as admits the growth of the modern *Zamia* and *Cycas*, remains of these genera being found here. This forest has been submerged; first, beneath the fresh waters of a lake or estuary, in which were deposited the Purbeck beds, and sands and clays of the Wealden formation (amounting together to nearly 1000 feet), and subsequently beneath the salt water of an ocean of sufficient depth to accumulate all the great marine formations of green sand and chalk that rest upon it.

1425. (8.) *Chalk formation with green sand*. This great deposit consists principally of chalk, with less extensive subjacent beds of green sand and tuffaceous chalk. It stretches, with little interruption, from Flamborough Head on the coast of Yorkshire, to near Sidmouth on the coast of Devonshire; forming a range of hills often of some hundred feet high, and of which the most precipitous face is generally on the north-west side. From this long range several ranges shoot toward the east and south-east. In some places the chalk forms hills, rising some hundred feet above the level of the sea; thus, Wilton Beacon, in Yorkshire, is 809 feet high; and Inkpen Beacon, in Wiltshire, the highest chalk hill in England, is 1011 feet above the level of the sea. Chalk does not often bear the character of a level or flat country; but, on the contrary, is subject to perpetual undulation of surface, the hills being remarkable for their smooth rounded outline, and the deep hollows and indentations on their sides. The most level tract of chalk in England is on the north-east and east of England.

1426. *The upper part of this formation*, through a great part of England, is characterised by the presence of common gun flint, arranged in thin beds or in variously-shaped masses, disposed more or less in parallel lines. In the lower part of the formation the flints become less and less abundant, and at length entirely disappear. This arrangement, however, is not always to be observed, for in some places the lower chalk abounds in flints. The lower part of the chalk formation, as already noticed at page 225., has in England received particular names: these are, *upper green sand*, immediately under the chalk; next the *gault* and *lower green sand*. In the chalk formation, the upper and middle parts are of chalk, while the lower and under are of sands, sandstones, and clays. The upper part may be considered an original deposit, the matter derived from the interior of the earth; the lower of a mechanical and alluvial nature. Chalk abounds in fossil remains of animals, and also contains fossilised plants. Corals in great variety, radiated animals, particularly echinites, are in vast numbers; shells of all the grand divisions and in great variety add to the zoological interest of the formation, which is further heightened by the fossil crabs, fishes, and reptiles, occasionally met with in it. The plants are *Conferæ*, *Fuci*, *Zosteræ*, *Cycadeæ*, with dicotyledonous wood perforated by some boring animal. The formation, as it occurs in England, appears to have been variously elevated and depressed at different times by some subterranean actions; but, as far as we know, it does not any where occur in contact with trap or other Plutonian rocks.

1427. III. *Tertiary rocks*. We owe to an intelligent observer, Mr. Webster, the first considerable series of observations on this class of rocks as met with in England. Since the account of the Isle of Wight by that gentleman, other English observers have made the tertiary deposits an object of study. Hitherto, in England, these deposits have been found only in what are called the *London basin* and the *Isle of Wight basin*; two spaces conjectured formerly to have had the basin shape, but now more or less filled with tertiary rocks; an opinion, however, which the late observations of Professor Buckland have shown to be less plausible than has been generally believed. The boundary of the first of these supposed basins may be stated, generally, as a line running from the inner edge of the chalk, south of Flamborough Head, in Yorkshire, nearly south, till it crosses the Wash, then south-west to the upper part of the valley of the river Kennet, near Hungerford, in Wiltshire; and thence trending south-east to the south of the Thames, and the north-west angle of the Isle of Thanet: in all these directions the boundary line is formed by the chalk hills; on the east side, the boundary is the coast of the German Ocean. The boundaries of the Isle of Wight

basin may be stated as follows: — on the north, a few miles south of Winchester; on the south, a little north of Carisbrook in the Isle of Wight; on the east, Brighton; and on the west, Dorchester. It is every where circumscribed by chalk hills, excepting where broken in by the channel between the Isle of Wight and the main land. The different members of the tertiary series met with in England, are named *Plastic clay*, *London clay*, *Bagshot sands*, the *Freshwater formations* of the Isle of Wight, and the *Crag*. — *Plastic clay*. This deposit consists of a plastic clay with gravel beds, alternating with beds of sand (sometimes in a state of sandstone) and clay. Its organic remains are principally marine shells, with layers of lignite or brown coal. — *London clay*. This is a bluish or blackish clay, sometimes so much impregnated with carbonate of lime as to form a kind of compact marl. Layers or nodules of septaria (a calcareous concretion) frequently occur in it. It is the great clayey deposit on which London is built. It has been bored to a depth of 700 feet; without reaching its bottom. The highest point it attains is the summit of High Beach in Essex, being 759 feet above the sea: Shooter's Hill, in Kent, is 446 feet high; Richmond Hill, and St. Ann's Hill, in Surrey, also consisting of this clay, are less elevated. It abounds in fossil organic remains from the animal as well as from the vegetable kingdom. Crocodiles, turtles, fishes, and crabs have been observed; but these are few in number compared with the host of fossil shells. These shells are often very beautifully preserved, frequently retaining the appearance of recent species. There are very few genera of recent shells which have not some representative in this formation, but the specific character is usually different; on the other hand, but few of the extinct genera, so frequent in the older formations, occur in this. The Isle of Sheppey, formed of London clay, affords a vast variety of fossil fruits and seeds. Mr. Crowe, of Eversham, is said to have collected from this remarkable spot 700 specimens, none of which are duplicates, and very few of which agree with any known seed vessels; many of them are conjectured to belong to tropical plants, some to the cocoa nut and spice tribes. Fragments of wood pierced by a shell animal, resembling the *Teredo navalis*, are met with; a fact which shows that the wood may have floated about in the sea. — *Bagshot sands*. These rest upon the London clay; they consist of sand, with greenish-coloured clay, variously coloured marls, containing grains of green sand, and fossil trochi and pectinites. — *Freshwater formations of the Isle of Wight and Hampshire*. The freshwater strata of the Isle of Wight are divided into two deposits by a rock characterised by the presence of marine remains, and named the *upper marine formation*, from being a supposed equivalent to the sands which intervene between the two freshwater deposits of Paris. The *lower freshwater* deposit of Binstead, near Ryde, consists of a limestone formed of fragments of freshwater shells, white shell marl, siliceous limestone, and sand. One tooth of an *Anaplotherium* and two teeth of a *Palæotherium* have been found in the lower marly beds of the quarries at Binstead. In the same quarries several rolled fragments of pachydermatous animals, and the jaw of an animal allied to the musk-deer tribe. In Colwell Bay the upper part of this deposit contains a mixture of freshwater and marine shells. The *upper marine formation*. — This deposit of calcareous beds abounds with freshwater shells in the lower part, but in the upper part we find marine shells; hence it is conjectured to have been formed in an estuary. *Upper freshwater formation*. — This consists principally of yellowish white marls. The organic remains are either freshwater or land. The geological history of the tertiary deposits in England has not yet been placed in direct connection with that of similar deposits on the continent of Europe. No trap or granite rocks have hitherto been met with in England any how connected with the tertiary strata.

1428. IV. *Alluvial rocks*. Nearly the whole of England is more or less covered with alluvium, or debris of previously existing rocks: thus it occurs on mountain ridges, and on the sides and bottoms of valleys; it is spread over plains, fills up, wholly or partially, fissures in rocks, and caves, and caverns, and forms beaches and other accumulations of greater or lesser extent on the sea coast. It varies in age, from the oldest, called *diluvium*, which stands in immediate connection with the *crag* or upper tertiary deposit, to the newest, those forming at present through the agency of the atmosphere, springs, lakes, rivers, and the waves and currents of the ocean. It encloses numerous remains of plants and animals, either more or less mineralised, or simply bleached: those of the oldest deposits appear to be of animals, and sometimes of plants, which are apparently extinct; while the newer enclose remains only of living animal and vegetable species. Although our limits do not allow us to enter into details on this very important and curious department of geology, we may remark, that the characters and modes of distribution of these alluvia are, in many instances, intimately connected with risings and depressions of the land; and consequently with apparent sinking and rising of the waters of the ocean, and the violent agitations sometimes induced in the great mass of the ocean, and also in lakes, by changes in the level of the solid parts of the globe.

SUBJECT. 2. *Botany.*

1429. *The botany* of the different parts of the British empire is so similar, that it is proposed to treat under one head that of England, Scotland, Ireland, and their adjacent islands.

1430. *The British Islands*, as regards their vegetable productions, are possessed of considerable interest, partly on account of their situation, their variety of soil and exposure, their great extent of coast, the height of many of the mountains; which, though of small elevation, as compared with those of the continent of Europe, yet, from their northern latitude, almost attain the elevation at which perpetual snow is found; and, above all, on account of the careful manner in which their botany has been explored. Were certain tribes of the Cryptogamia, especially the Fungi and the Algæ, more satisfactorily studied and described, we should possess, in the works of Sir James Smith, the most correct flora, of any country in the world. Yet, with all these advantages, few countries have been less known in respect to the distribution or peculiar localities of these plants. Turner and Dillwyn, in their work called the *Botanist's Guide*, have, indeed, done much towards making known the particular stations, especially of the rare plants of England and Wales. M. Boué, in his inaugural thesis, printed at Edinburgh in 1817, on the botany of Scotland, has been the first to offer any remarks on a geographical arrangement, however partial, of the vegetables of that portion of the kingdom; and this was followed by the very useful Essay of Mr. Winch, on the geographical distribution of plants throughout the counties of Northumberland, Cumberland, and Durham; and by Mr. Atkinson on that of Yorkshire, published in the *Transactions of the Wernerian Society*. Aided by these, and some valuable communications that have been made to us by our friends, and by our personal observations, made during various excursions in different parts of the British dominions, we shall endeavour to throw together such remarks as may, at some future time, lay the foundation for a geographical distribution of our vegetables, upon a more extended scale.

1431. *The principal of these islands* in question, Great Britain, although its breadth from E. to W. scarcely averages 8° , yet extends from lat. 50° in the S. to $58^{\circ} 40'$, or, if the extreme northern point, where it is broken into a number of smaller islands, be taken into consideration, to N. lat. 61° : it thus, necessarily, even in its plains, includes a considerable variety of climate, but every where, more or less, tempered by the surrounding ocean; so as, in no part of the island, except on the mountains, or high table-lands, can the temperature be compared, in point of climate, to similar latitudes upon the European, much less upon the American continents. Yet, from the proximity of the whole group to the former, the vegetation is, with a very few exceptions, hereafter to be mentioned, altogether similar to that of the adjacent districts of Europe. In one point of view, indeed, our insular situation affects vegetation in a way which could hardly be expected in so high a latitude; and if, on the one hand, in consequence of our unfavourable summers, the frequent obscurity of the sun, our damp and foggy atmosphere, we are not permitted, without artificial heat and protection, to bring many of the fruits of more favoured climates to perfection; yet the mildness of our winter enables us to introduce and to naturalise plants of much more southern latitudes: so that our gardens, our parks, our shrubberies, and even our forests, are adorned with a vegetation the most varied that can be imagined, or producing the most beautiful flowers, or the most valued of the timbers.

1432. *If there be a spot in our island* which may be designated "a land of the cypress and myrtle, the cedar and vine," it is on the *extreme southern coast of England and Ireland*, yet not assuredly "where the trees ever blossom, the beams ever shine;" but in a spot, certainly, where the native vegetables of the warmer temperate zone are successfully grown in the open air, and where they come to considerable perfection. We have ourselves seen, in the south of Devonshire, the orange and lemon trees loaded with fruit of the finest kind; trained, indeed, to a wall, but without protection, and only provided with it during a very short portion of the winter months; the Lemon-scented Vervain (*Lippia citriodora*, formerly called *Verbena triphylla*) becomes quite a tree, without any artificial protection; the American Agave, the Creeping Cereus, the Prickly Pear, the former having twice flowered in the grounds of the same gentleman, Mr. Yates of Woodville, near Salcombe. The account of the latter of these is recorded in the *Transactions of the Horticultural Society of London*, for 1822; and the plant itself is of that extraordinary character and the circumstance of its blossoming at such an early age is so characteristic of the climate, that we shall here record some of the most important particulars respecting it. It was planted in the open ground, in 1804, when only three years old, and about 6 inches high, within a few yards of the sea-shore, at an elevation of about 40 or 50 feet above the level of the sea; and it was never, in any way, artificially sheltered, nor aided by manure or any cultivation. In eight years from that period, it had attained the height of 5 feet, and during the summer of 1812, it grew nearly $\frac{1}{8}$ of an inch daily. In 1820, it was 11 feet high, and covered a space, the diameter of which was 16 feet; the leaves, close to the stem, being nearly 9 inches thick. During that year it threw up its flowering stem, at first resembling a great head of

asparagus, which, for six weeks, rose at the rate of 3 inches a day. By the end of September the flower-stalk attained the height of 27 feet, sending out side branches, and blossoming throughout the whole of the months of September and October. The number of flowering branches was 40, the lowest projecting 2 feet in horizontal length from the stem, gradually diminishing upwards to about a foot or 9 inches at the top; each of them had between 300 and 400 flowers; and in all, there were above 16,000 blossoms. The base of the flowering stalk was 20 inches in circumference.*

1433. *Myrtles*, from the south of Europe, the Tea, Camellias and other Chinese and Japanese plants, thrive well in the open air, as well as the Magnolias, and many other trees, from the southern states of North America, whose native latitudes lie many degrees nearer to the tropics than the highly favoured line of coast in question.

1434. *A beautiful picture of the exotic vegetation* of the island of Guernsey is given by Dr. Macculloch, in the *Memoirs of the Caledonian Horticultural Society*. He justly states, that the Guernsey Lily (*Amaryllis sarniensis*) is not a native of that island, but, as it is supposed, was introduced by accident or design from Japan, and cultivated there to a vast extent to supply the London market. The climate seems to be peculiarly favourable to its growth and increase, as it is for those of other species of the same genus; the *Amaryllis vittata*, *Belladonna undulata* and *formosissima* natives of the Cape or South America. The *Magnolia grandiflora* is as certain to flower yearly, as it is remarkable for the luxuriance of its growth. The Garden Hydrangea (*H. hortensis*), the Scarlet Fuchsia (*F. coccinea*), the Horseshoe Geranium (*G. zonale*, *G. inquinans*, *G. radula*, and *G. glutinosum*), emulate in summer the luxuriance which they display in their native climates. Every rustic cottage is covered with Geraniums, and adorned with numerous kinds of Pinks, such as are rarely seen in the rest of Britain, except among careful florists. The Lemon-scented Vervain here, too, flourishes perfectly exposed, and grows to 20 feet high and upwards, spreading in a circle of which the diameter equals its height, with its long branches reaching down to the ground on all sides. Its growth, indeed, is so luxuriant, that it is necessary to keep it from becoming troublesome, by perpetually cutting it about the root, from which fresh shoots, 14 feet long, resembling those of the Osier Willow, are annually produced. The *Celtis micrantha*, a stove plant, flourishes, with little care, out of doors; the double and single Camellias, some species of Olive, as well as many Proteas, several kinds of Cistus, particularly *C. crispifolius* and *formosus*, Yuccas, the Azorian Jessamine (*Jasminum azoricum*), the Oleander (*Nerium Oleander*), the *Daphne odora*, *Clethra arborea*, *Corræa alba*, *Melaleuca hypericifolia*, *Galardia rigens*, with numerous *Ixias* and Heaths, all equally requiring the protection of the green-house during the severer winters of our own island, and many of them liable to perish, in spite of our greatest care, — all these, as well as the Myrtle, brave the utmost rigour of a Guernsey climate, and flourish in the greatest luxuriance.

1435. *The Indian Shot* (*Canna indica*) has become thoroughly habituated to the climate of Guernsey, and scatters its seeds, every year, so as to prove a weed in the gardens where it has been introduced. The effect of this delightful climate is visible, too, on fruits of various kinds. Both the Seville and the Sweet Oranges, standing under the shelter of a wall, and only protected by a mat in winter, produce fruit in abundance every year.

1436. *What we have been stating* of the climate of the extreme south of Britain is, however, a remarkable exception to that of the rest of this kingdom; and even in that part such productions are only witnessed upon the very verge, as it were, of the ocean. A few miles inland, and the climate, rather than the natural vegetation, undergoes a considerable change. The lines which constitute the northern boundaries in Europe of the Maize and the Vine (the former especially), are considerably to the south of England; nor is there a chance of these two valuable products ever being cultivated with success in such high latitudes as the British isles; and especially when the fickle character of the summer is taken into account. It is only by art that the fruits of southern climes can, generally speaking, be brought to perfection with us; and such are the skill and assiduity of our gardeners, and such the encouragement given to them by public institutions, and by the nobility and men of large fortune, that in no part of the world is better fruit to be met with, either with regard to size or to flavour.

* In Spain, especially near the shores of the Mediterranean, the flowering stems of the *Agave americana* grow to 30 feet in height, in a period of ten days, as we are assured by a friend who has recently returned from that country; and they have all the appearance of a forest of ships' masts. In South America, they are applied to many valuable purposes; cut into slices, they are employed in various parts of the country as razor strops, and are sold at Rio Janeiro for that purpose. Like many other monocotyledonous plants, these stems probably abound in silex, which acts upon the blade of the knife or razor. The young stalks are so hard that they cannot be cut with a large and strong knife; and the fibres of the leaves are manufactured, at Perpignan, into ropes and cordage. In Catalonia, the *Agave americana* flowers in its ninth or tenth year; in the south of France so much more rarely, that it is there called "the plant that flowers as seldom as an Englishman smiles." In our country it is outvied, we hope, by the smiles of the natives; for, as we have before stated, it blossomed, in Devonshire, in its twenty-first year; whereas, in the rest of England, in the green-house, or even stove, it flowers so unfrequently, that it is called "the plant that flowers once in a hundred years."

1437. *Before, however, we speak further of the exotic productions, which are affected by the different latitudes or by the different elevations in Great Britain, we must be permitted to offer a few remarks on its native vegetation; which (exclusive of cryptogamia) has been so admirably described by Sir James E. Smith, in his English Flora, the last, and, we may add, too, the best, of the many excellent works of that learned botanist.*

1438. *The general nature of the vegetation of the British isles will be best seen by a table of the different natural families, accompanied by columns, referring to the number of species in each of these groups; and the proportion which each of these latter bears to the whole.*

1439. *So widely different as is our flora, and, indeed, that of the greater part of Europe, from that of America, in the same latitude, the comparison of the vegetable productions of the two countries would be attended with no interesting results; nor do we think that, to institute a comparison between that of Britain and of any country on the continent of Europe, either to the north or south of our own islands, would repay the labour of the investigation; but, did our space allow us, we should gladly have scrutinised the relation between the vegetation of our own islands, and that of an equal space of territory, as far as it would be possible, in the same degrees of latitude; in Germany and Denmark, and a part of Sweden, for example. But this would, doubtless, be attended with great labour. Many floras would have to be consulted, and only such plants selected as belong to the given space of country. Nor would the comparison be exactly fair, unless the two districts contained, and in nearly the same parallels of latitude, similar mountains and similar plains. A great obstacle, too, to the obtaining of correct results would arise from the very different opinions which different botanists entertain as to what are species, and what varieties; and what are aboriginal natives, and what imported from other countries; so that no two naturalists, even publishing at the same time the flora of the same region, would at all approximate in what concerns the number of native species in that region, more especially if each uses his own eyes, and is unbiassed by the opinion of his fellow-labourer in the same studies. Nees von Esenbeck and Hornschuch's *Bryologia Germanica*, contains, in the first volume, but few genera, and comprises 68 species: the same group of genera in Mohr's *Flora Germanica* has only half that number. In our own country, Smith reckons 17 saxifrages of Scotland, 59 willows, and 14 roses; Hooker, in his *Flora Scotica*, enumerates but 13 saxifrages, 10 roses, and 43 willows; and the same holds good with many other genera in different writers. At present, we can only guess, from a tolerable acquaintance with the vegetable productions, at the relative proportions; and whatever may be our partiality to our native land, we must, nevertheless, express our opinion that the result of such an investigation would be greatly in favour of the Continent. The soil, we apprehend, is more varied, the quantity of uncultivated ground is greater, and the very circumstance of its continuity of land, extending north and south and eastward, would naturally aid the migration of plants from great distances, which must materially increase the number of species. Thus it is, that, on landing on the shores of France or Holland, we find many plants which have reached their limits in those directions, simply in consequence of the barrier afforded by the sea; whereas the same individual species passes on to Germany, Holland, and even to Denmark and Sweden, to enrich those more northern floras.*

1440. *The only two floras of Great Britain, which are so complete as to demand our particular attention, are Smith's work, above alluded to the (*English Flora*), and Gray's *Arrangement of British Plants*; the former classed according to the Linnæan system, extending, however, only to the end of the class Polygamia, and the first order of the class Cryptogamia Filices. Gray's *Flora* includes the whole of the British vegetables, arranged according to the natural method, and is the only one that approaches, however deficient it may still be, to any thing like a catalogue of our present state of knowledge of the Cryptogamia. Among the Phænogamous plants, however, Mr. Gray has included a great number that are only known in a state of cultivation, as has been done by De Candolle, in his *Flore Française*, and many other continental botanists. We have, therefore, deemed it convenient thus to give a list of the plants, according to each of these authors; and the increased number in the columns of species, according to Mr. Gray, will be thus easily accounted for.*

COMPARATIVE TABLE.

A List of the Number of Species of British Plants, arranged according to the Classes and principal Families to which they belong; exhibiting the relative proportion which these latter bear to the whole of the respective Classes.*

Names of the Natural Families.	Species in Smith's <i>English Flora</i> .			Proportion of Natural Orders to Phænoga- mous, per Smith.	Species in Gray's <i>Arrangement of British Plants</i> .			Proportion of Natural Orders to Phænoga- mous, per Gray.	Average Proportion of Natural Orders to Phænogamous Plants.

1441. *Scotland*, comprising the northern extremity of the island, commencing in latitude 55°, and its flora having been tolerably satisfactorily investigated, we here subjoin a similar list, drawn up by Mr. Arnott. The Phænogamous plants are taken from the *Flora Scotica* of Dr. Hooker; the Cryptogamia from the *Flora Scotica*, the *Flora Edinensis*, and *Cryptogamic Flora* of Dr. Greville, and from the late Captain Carmichael's manuscripts.† It will be observed that the Musci, Filices, Lichenes, and Hepaticæ have of late years received comparatively few additions; while the Algæ and Fungi have increased so enormously, that more are now reckoned for each order than Gray has stated as natives of the whole island.

* Kindly drawn up for this work by G. A. W. Arnott, Esq. of Edinburgh.

† The proportions in the Cryptogamia will be found probably much more correct for Scotland than those given in the British table are for the whole of Britain; and this owing to the very accurate researches which have been made in that tribe by Dr. Greville, and by the late Captain Dugald Carmichael; particularly by the latter in the Fungi and Algæ; so that the discoveries of that gentleman alone in those two groups, in one small district (Appin) in the west highlands of Scotland, amount to more species than were previously described as inhabiting the whole of the British dominions.

Names of the Natural Families.	Species.			Proportion of Natural Orders to Phanogamous Plants.	Names of the Natural Families.	Species.			Proportion of Natural Orders to Phanogamous Plants.

1442. It must be remarked, that in *Cyperaceæ*, *Junceæ*, *Salix*, *Saxifraga*, *Rosa*, *Rubus*, and some others, the species are not formed on the same rules as in Smith's *English Flora*; and therefore, before drawing a parallel between these orders in Scotland, and in the whole of Britain, a considerable number of species ought to be added. To make this comparison, then, about twenty species may be added to the *Monocotyledones*, and about fifty (say forty-seven), to the *Dicotyledonous* plants, making these two, 280 and 870; whence the *Monocotyledones* of Scotland are to the whole of those in the British dominions as one to one and a quarter, or as four to five; and the *Dicotyledones* as eight to eleven.

1443. Ireland possesses a flora which partakes of the nature of those of England and Scotland. A list of the phænogamous plants has been recently published by Mr. J. T. Mackay, of the Dublin College Botanic Garden. It exhibits a much poorer vegetation than its sister island, including only 934 species; of which there are,

41 Filices. 211 Monocotyledones, and 682 Dicotyledones.

So that the proportion of Filices to Phanogamous plants is as - 1 : 21 $\frac{1}{2}$
Monocotyledones to Phanogamous plants 1 : 4 $\frac{1}{2}$
Dicotyledones to Phanogamous plants 1 : 1 $\frac{1}{2}$

1444. The proportion of Irish Monocotyledones to British Monocotyledones (according to the species of Smith) is as - 1 to 1 $\frac{3}{5}$, or as 3 to 5.
Of Irish Dicotyledones - 1 to 1 $\frac{3}{5}$, or as 3 to 5.

1445. If we take into consideration the plants of the northern part of England, according to the species in Mr. Winch's list of the plants of Northumberland, Cumberland, and Durham, we shall find that there are 47 *Filices*; other *Cryptogamia*, 1206; *Monocotyledones*, 249; and *Dicotyledones*, 788; so that the total *Cryptogamous* to Phanogamous plants are as - 1 to $\frac{1}{2}$

Filices to ditto - - - 1 to 22
Monocotyledones to ditto - - - 1 to 4 $\frac{1}{2}$
Dicotyledones to ditto - - - 1 to 1 $\frac{1}{2}$

Or, if compared with the whole of the British empire:—

Monocotyledones to British Monocotyledones (by Smith's *Flora*) as 1 to 1 $\frac{1}{2}$, or as 5 to 7.

Dicotyledones to British Dicotyledones (by Smith's *Flora*) as 1 to 1 $\frac{1}{2}$, or as 2 to 3 nearly.

1446. Proportion of the Classes of Plants to the Phanogamous:—

Names of the Natural Families.	Great Britain and Ireland. (Smith.)	Scotland. (Hooker, &c.)	Ireland. (Mackay.)	N. of England. (Winch.)
Dicotyledones - -	1 to 1 $\frac{1}{2}$	1 to 1 $\frac{3}{10}$; or nearly 1 to 1 $\frac{1}{2}$	1 to 1 $\frac{1}{2}$	1 to 1 $\frac{1}{2}$
Monocotyledones - -	1 to 4 $\frac{1}{4}$	1 to 4 $\frac{1}{8}$	1 to 4 $\frac{1}{4}$	1 to 4 $\frac{1}{8}$
Acotyledones (including Filices) - -	1 to $\frac{1}{2}$	1 to $\frac{1}{2}$	unknown.	1 to $\frac{1}{2}$
Filices - -	1 to 26	1 to 22 $\frac{1}{2}$	1 to 21 $\frac{3}{4}$	1 to 22

1447. Relative proportion of species in —

Names of the Natural Families.	Great Britain and Ireland. (Smith.)	Scotland. (Hooker.)	Ireland. (Mackay.)	N. of England. (Winch.)
Dicotyledones - -	28	20	17	19
Monocotyledones - -	36	26	21	25

1448. Few, indeed, of the 3300 (taking them in round numbers) species of plants now enumerated as natives of England, Scotland, and Ireland, and the adjacent islets, can be considered as exclusively belonging to these countries. For though there are many which are not referred to as species in the works of other authors, yet

they are, for the most part, among such families as are not well understood, and about which there will always exist a difference of opinion; as among the Grasses, Willows, Brambles, &c. The Scottish and Cornish Lovages (*Ligusticum scoticum* and *cornubiense* Sm.) were long considered to be peculiar to the British dominions; the one in the extreme south, the other in the north; but the former is now well known to be an inhabitant of maritime places in all the arctic and subarctic regions, so that it has only in Scotland and the north of England found its southern limits; whilst the latter, which we have received from Italy, and which grows also in Greece and Portugal, has, in Cornwall, reached its extreme northern boundary. The place of the Bird's-eye Primrose (*Primula farinosa*), so abundant in pastures in the north and west of England, is supplied by the *Primula scotica* in the northern districts of Scotland, and in the Orkney Islands: it is unquestionably a distinct species; but we are confident, from the excellent representation of it in the *Svensk Botanik*, that it is also a native of Sweden, though there confounded with *P. farinosa*. These instances will suffice to show with what great caution we ought to look upon any plant which may have been considered to belong exclusively to the British dominions.

1449. Many plants have indeed reached their northern limits in the south of England and Ireland. We must particularly mention the Strawberry Tree (*Arbutus Unedo*, fig. 107.), which forms so charming a feature

107

STRAWBERRY TREE.

the Mezereum (*Daphne Mezereum*); the Flowering Rush (*Butomus umbellatus*); the Yellow Marsh Saxifrage (*Saxifraga Hirculus*); though on the Continent a very arctic plant, the Clove Pink (*Dianthus caryophyllus*); and *D. prolifer*, several Catchflies (*Silene*); Euphorbias, Cistuses, Anemones, the Traveller's Joy (*Clematis Vitalba*); the Ground Pine (*Ajuga Chamapitys*); the Wood-Sage (*Teucrium Scorodonia*); the crested and field Cow-wheat (*Melampyrum cristatum* and *arvense*); some Orobanches, the Vella annua, *Draba aizoides*, and *Iberis amara*, some Fumitories (*Fumaria solida*, *lutea*, and *parviflora*); the yellow and crimson Vetchlings (*Lathyrus Aphaca* and *Nissolia*); the Vicia hybrida, lævigata, and bithynica, *Hippocrepis comosa*; *Orchis Morio*†, *pyramidalis*, *ustulata*, *fusca*, *militaris*, *tephrosanthos*, *hircina*; *Aceras anthropophora*, *Herminium monorchis*; all the species of *Ophrys*, *Epipactis rubra*, *Malaxis Loeselii*; the beautiful and rare Lady's Slipper (*Cypripedium Calceolus*); the Birthwort (*Aristolochia Clematidis*); the Roman Nettle (*Urtica pilulifera*); the Xanthium strumarium and *Amaranthus Blitum*; the Spanish Chestnut Tree (*Fagus castanea*); and Misseltree (*Viscum album*); the Sea Buckthorn (*Hippophae rhamnoides*); and White Poplar (*Populus*

indeed, supposed that it was introduced into Ireland by the monks of Mucross Abbey, at some very remote period. Its appearance is, however, altogether that of an aboriginal native, coming to a great size*, perfecting its bright scarlet berries, which are disseminated over the rocks and islands in every direction. The *Erica vagans*, or Cornish Heath (fig. 108. a), is found nowhere in Britain except Cornwall; and the same may be said of the newly-discovered *E. ciliaris* (b), and the following, of great beauty or rarity: *Lobelia Dortmann*, *Phyteuma orbicularis* and *P. spicata*, *Sibthorpia europæa* and *Isardia palustris*, are quite southern plants in the British dominions.

1450. The Water-Soldier (*Stratiotes aloides*); the Water Violet (*Hottonia palustris*); the small Maidenhair Grass (*Briza minor*); the Sweet Violet (*Viola odorata*); several Mulleins, the Primrose-peerless (*Narcissus poeticus* and *biflorus*); the common Snake's Head (*Fritillaria meleagris*); the Agrostis setacea, the Star of Bethlehem (*Ornithogalum pyrenaicum*); the two species of Squill (*Scilla autumnalis* and *bifolia*); the Mountain Spiderwort (*Anthericum serotinum*); the Solomon's Seal (*Convallaria polygonatum*); and Sweet Sedge (*Acorus Calamus*); the Yellow-wort (*Chlora perfoliata*); the Yellow Marsh Saxifrage (*Saxifraga Hirculus*); though on the Continent a very arctic plant, the Clove Pink (*Dianthus caryophyllus*); and *D. prolifer*, several Catchflies (*Silene*); Euphorbias, Cistuses, Anemones, the Traveller's Joy (*Clematis Vitalba*); the Ground Pine (*Ajuga Chamapitys*); the Wood-Sage (*Teucrium Scorodonia*); the crested and field Cow-wheat (*Melampyrum cristatum* and *arvense*); some Orobanches, the Vella annua, *Draba aizoides*, and *Iberis amara*, some Fumitories (*Fumaria solida*, *lutea*, and *parviflora*); the yellow and crimson Vetchlings (*Lathyrus Aphaca* and *Nissolia*); the Vicia hybrida, lævigata, and bithynica, *Hippocrepis comosa*; *Orchis Morio*†, *pyramidalis*, *ustulata*, *fusca*, *militaris*, *tephrosanthos*, *hircina*; *Aceras anthropophora*, *Herminium monorchis*; all the species of *Ophrys*, *Epipactis rubra*, *Malaxis Loeselii*; the beautiful and rare Lady's Slipper (*Cypripedium Calceolus*); the Birthwort (*Aristolochia Clematidis*); the Roman Nettle (*Urtica pilulifera*); the Xanthium strumarium and *Amaranthus Blitum*; the Spanish Chestnut Tree (*Fagus castanea*); and Misseltree (*Viscum album*); the Sea Buckthorn (*Hippophae rhamnoides*); and White Poplar (*Populus*

108

CORNISH HEATH.

CILLATED HEATH.

canescens): these are some among the most striking of the British plants, which do not reach the middle of the kingdom, and fail below the south of Scotland.

1451. The most interesting of the Scottish plants are, principally, such whose types are found on the continent of Europe, in high northern latitudes, or in the extreme arctic regions of both Asia and America;

109

a, SCOTTISH PRIMROSE.
c, SINGLE-FLOWERED WATER-GREEN.b, ROCK SCORPION GRASS.
d, SMALL ALPINE GENTIAN.

such as *Veronica fruticulosa*, *saxatilis*, and *alpina*, several alpine grasses, and other glumaceous plants; such as *Phleum alpinum* and *Alopecurus alpinus*, *Eriophorum alpinum*; *Juncus castaneus*, *arcticus*, and *biglumis*; and *Luzula arctica*, *Primula scotica* (fig. 109. a), the *Myosotis alpestris* (d), *Azalea procumbens*, *Gentiana nivalis* (c), *Sibbaldia procumbens*, *Convallaria verticillata*, *Epilobium alpinum*, *Arbutus alpina*, *Pyrola uniflora* (b), *Saxifraga nivalis* and *rivularis*, *Stellaria scapigera* (the latter is exclusively British), *Arenaria rubella* and *fastigiata*, the *Cherleria sedoides*, *Lychnis Viscaria* and *alpina*, *Spergula saginoides*, *Potentilla opaca*, *Nuphar Kalmiana*, *Ranunculus alpestris*, *Ajuga pyramidalis*, *Cardamine bellidiflora*, *Orobanchis niger*, *Astragalus tralensis* and *campestris*, *Erigeron alpinus*, *Corallorhiza innata*, *Achillaea tomentosa*, *Goodyera repens*; the most alpine *Carices* and *Salices*, and the Dwarf Birch (*Betula nana*).

1452. There are two plants which deserve particular notice, as natives of Great Britain, and found nowhere else in Europe; but these are again met with in North America; the one is *Potentilla tridentata* (fig. 110. a) abundant in arctic America and upon the Rocky and White

* Mr. Mackay measured a trunk of this fine evergreen tree on Rough Island, nearly opposite O'Sullivan's Cascade, which, in 1805, was 9½ feet in girth, at a foot from the ground.

† On the authority of Lightfoot, indeed, this plant, so abundantly found in England, is given as a native of Scotland; but no living botanist, that I am aware of, has ever seen it there.

Mountains, the other the *Eriocaulon septangulare* (fig. 110. *b*). This latter genus is mostly tropical, or a native

a, TRIFID-LEAVED CINQUEFOIL.
b, JOINTED PIPEWORT.

of the warm temperate zones in America, the East Indies, and Australia. The only exceptions to this rule are the *Eriocaulon pellucidum* of Michaux, and the plant in question; the former being found in North America as high as Canada; and, upon examination, the two species prove identical. In these instances, the *Eriocaulon* and the *Potentilla* seem to have overcome many obstacles in their migration, and to have reached their eastern boundary. The *Eriocaulon* is confined to a few lakes in the Hebrides, where we have been surprised in the month of September at the high temperature of the water, which probably never freezes; and in some spots in the south and west of Ireland: the *Potentilla* is only found on one hill in Angushire.

1453. It is worthy of remark, that the genus *Pedicularis*, which is so numerous in species, in the eastern and southern parts of Europe, almost wholly disappears in Britain; for, notwithstanding the vast numbers of it which are found in Siberia, the south of Russia, Switzerland, extending even to the Pyrenees, and Germany, our country possesses but two, which are equally abundant upon the Continent; and although almost wholly an alpine genus, yet our mountains possess not one really alpine species. It would appear that the climate is peculiarly unsuited to their nurture; for in North America, in the same and especially in still higher northern latitudes, they again become abundant.

1454. Ireland, again, exhibits a few striking peculiarities in some of its vegetable productions. Besides the Strawberry tree (*Arbutus unedo*) already mentioned, it can boast of *Pinguicula grandiflora* (fig. 111. *a*), a beautiful flower, native of France and the Pyrenees; *Menziesia polifolia* (*b*), a species belonging to the latter country and to Spain, and found in a wild state in no other parts of the world; it is, too, a most lovely one: also St. Patrick's Cabbage (*Saxifraga umbrosa*) and the London Pride (*S. Geum*, *c*) and their varieties, which are scarcely known to exist but in Switzerland and the Pyrenees; *Arenaria ciliata*, a native of the mountains on the continent of Europe; and to these rarities have lately been added, by Professor Giesecké, the Yellow Poppy (*Papaver nudicaule*, *d*), and the *Ledum palustre*

a, LARGE-FLOWERED BUTTERWORT.
d, NAKED-STALKED YELLOW POPPY.

b, IRISH MENZIESIA.
c, MARSH LEDUM.

c, KIDNEY-LEAVED SAXIFRAGE.

(*c*), both of them peculiarly arctic productions, and plentiful on the northern extremity of America and Greenland; and with these we must be permitted to number, though Cryptogamic plants, the

a, TRUE MAIDEN-HAIR.
b, SHORT-STYLED BRISTLE-FERN.

Trichomanes brevisetum (fig. 112. *b*), which scarcely grows any where else in the world but in Madeira and in Yorkshire (if it be not now extinct in the latter habitat), the *Adiantum Capillus Veneris* (*a*), whose only locality in the British dominions is the west of Ireland, and one spot in Wales, but which is frequent in the south of Europe, and even in the tropical parts of America; and two mosses, *Hookeria latevirens*, and *Daltonia splachnoides*, entirely peculiar to Ireland.

1455. *Hibernia*, again, possesses three remarkable vegetable productions, which are now, we believe, pretty generally distributed in our gardens and shrubberies throughout the kingdom, and are universally known by the names of the Irish Broom, Irish Furze, and Irish Yew. The former, we believe to be the *Sparticum patens* of Linnæus, a Spanish species, with very hairy pods; and it is, probably, not wild in that country. The Irish Furze has an appearance very different from that of the European or Dwarf Furzes (*Ulex europæus* and *nanus*), having very erect short branches, and closely placed spines; so that the whole plant has a remarkably dense and compact habit, appearing almost as if it were kept close clipped with shears. It blossoms rarely, but we have seen both flowers and seed-vessels, which do not differ in any material point from those of *Ulex nanus*. In some gardens it is called *U. europæus* var. *strictus*; but Mr. Mackay, perhaps with justice, considers it to be quite a distinct species, and he has called it, in his "Catalogue of the Indigenous Plants of Ireland," *Ulex strictus*. Still, the

only stations for this plant are in the Marquess of Londonderry's park and shrubberies, at Mount Stewart, county of Down, where there are some very large bushes; but whence it came, no one can tell. This would, however, be a very valuable plant to the agriculturist; for, according to Mr. Stewart Murray, it has been planted (for it increases readily by cuttings) in dry hilly pastures in the north of Scotland, and in the early spring throws up an abundant crop of succulent shoots, which are greedily eaten by the sheep, when there is little or no grass to support them.

113

IRISH YEW.

1456. *The third Irish botanical curiosity* is the Irish Yew (fig. 113), or Florence-Court Yew, as it is called in that country, from its being first discovered at Florence Court, the seat of Lord Enniskillen. Mr. Mackay does not consider it to be wild; but Mr. Hervey, in the *Agricultural Magazine* for October, 1828, says, that it is an undoubted native, and plentiful in the neighbourhood of Antrim, where there are trees at least a century old. It is distinguished by its upright branches, which give the whole plant somewhat the habit of a Cypress; by the leaves growing, not in a distichous manner, but from all sides of the stem: the drupe or berry, too, Mr. Mackay says, is of a different form from that of the common Yew.

1457. *If we had room here for its insertion*, we would gladly have drawn up a full list of those plants which are exclusively peculiar to the east or to the west sides of this kingdom, or which have, at least, their maximum in either one, and are very rare or altogether wanting on the opposite side. We are sure it would be productive of highly interesting results. The hasty catalogue which follows, though made without the accurate care which the subject would require, if it received the scrupulous attention which it merits, will, nevertheless, suffice to show that the plants of the east coast, generally, have the character of those which are natives of dryer and warmer climates; whereas those of the west are, in most instances, types of the subalpine plants of more southern latitudes, or exhibit a vegetation analogous to that of the more southern coasts of France and the Mediterranean. It must be observed, however, that it is extremely difficult to define the limits of the verge of the plants on the east or west coast, for want of more full stations than we are yet possessed of, and more ample local floras; and it must be clearly understood that the annexed list must be considered only as an approximation to the truth, even upon its own limited scale.

1458. *Plants* which are either wholly confined to the east side of England, or have their maximum there, rarely extending to the centre of the kingdom:—

Veronica triphylla
— verna
Dactylis stricta
Polypogon monspeliensis
— littoralis
Alopecurus bulbosus
Panicum sanguinale
Agrostis Spica venti
Dipsacus pilosus
Holosteum umbellatum
Gentiana verna
Tillæa muscosa
Bupleurum tenuissimum
— rotundifolium
Menyanthes nymphæoides
Pimpinella magna
Myosurus minimus

Verbascum
Campanula patula
— Rapunculus
Thesium linophyllum
Salsola fruticosa
Statice reticulata (differs
from the plant so
called of Scotland and
Wales)
Tofieldia palustris
Acorus Calamus
Luzula Forsteri
Fritillaria meleagris
Tulipa sylvestris
Ornithogalum nutans
— umbellatum
— luteum

Trientalis europæa
Dianthus caryophyllus
Sedum album
Silene quinquevulnera
— conica
— anglica
— noctiflora
Lythrum hyssopifolium
Adonis autumnalis
Anemone Pulsatilla
Glaucium violaceum
Stratiotes aloides
Ajuga alpina?
— Chamæpitys
Melampyrum cristatum
— arvense
— sylvaticum

Orobanche minor
— ramosa
Turritis glabra?
Orchis fusca
— militaris
— taphrosanthos
— ustulata
— hircina
Ophrys muscifera
— apifera
— arachnites
— aranifera
Aristolochia clematidis
Hippophae rhamnoides
Urtica pilulifera
Atriplex pedunculata.

1459. *Plants* which are either wholly confined to the western side of England, or to Wales, or which have their maximum there, rarely extending beyond the centre of the kingdom:—

Pinguicula lusitanica
Polycarpon tetraphyllum
Knappia agrostidea
Scirpus Holoschænus
Rubia peregrina
Lysimachia thyrsiflora
(Yorkshire and Scotland)
Campanula hederacea
Lobelia Dortmanna
— urens (but not so
in Scotland)
Pulmonaria maritima,
(found as far south as
Devonshire*; not con-
fined to either coast of
Scotland)

Primula farinosa (most a-
bundant in Cumberland;
in Scotland confined to
the east, and rare)
Impatiens noli tangere
Gentiana campestris
Corrigiola littoralis
Exacum filiforme
Eryngium campestre
Sium verticillatum
Sibthorpia europæa
Bupleurum Odontites
Illecebrum verticillatum
Anthericum serotinum
Scilla verna
— autumnalis

Rumex digynus
Juncus filiformis
Saxifraga nivalis (Wales
and Yorkshire)
Cotyledon Umbilicus
Oxalis corniculata
Andromeda polifolia
Arenaria tenuifolia
Cotoneaster vulgaris
Papaver cambricum
Cistus polifolius
— guttatus
— marifolius
Actæa spicata
Melittis melissophyllum
— grandiflorum

Bartsia viscosa
Brassica oleracea
— monensis
Draba aizoides
Cheiranthus sinuatus
(Anglesea)
Arabis hispida
Erodium moschatum
Vicia bithynica
Lotus diffusus
Chrysocoma aurea
Euphorbia Peplis
Asplenium septentrionale
(Denbighshire; in Scot-
land, east?)
Adiantum Capillus Veneris.

1460. *In general, with regard to such of the plants* above mentioned as are found in Scotland, the same rule, as to locality, holds good in that country also. There are, however, some differences, and a few unexpected peculiarities, which we shall shortly notice; and Scotland being of so much smaller extent, and perhaps more thoroughly investigated, than England, we can speak with more certainty as to the range of these vegetables.

1461. *Plants* found on the west side of Scotland almost exclusively:—

Pinguicula lusitanica
Lysimachia Nummularia
Convolvulus Sepium
Campanula hederacea
Jasione montana
Selinum palustre
Sium verticillatum

Ceanothe pimpinelloides
Statice Limonium
Drosera longifolia
Epilobium tetragonum
Dianthus deltoideus
Cotyledon Umbilicus
Lythrum Salicaria

Glaucium luteum
Thalictrum flavum
Bartsia viscosa
Brassica monensis
Ervum tetraspermum
Hypericum Androsæmum
— elodes

Picris hieracioid
Inula crithmoides
Epipactis latifolia
Gymnadenia conopsea
(very rare on the east
coast).

* According to Turner and Dillwyn's *Botanist's Guide*.

1462. *Plants found on the east side of Scotland almost exclusively:—*

Phleum arenarium	Saxifraga tridactylites	Marrubium vulgare	Vicia lutea
Festuca loliacea	Silene noctiflora	Lavatera arborea	Cnicus Eriophorus
Echium vulgare (doubt- fully wild on the west)	Euphorbia Esula	Astragalus glycyphylus	Onopordon Acanthium
Primula veris	— exigua	— hypoglottis	Artemisia maritima
— elatior	Arenaria verna	Trifolium fragiferum	Epipactis palustris
Convolvulus arvensis	Potentilla verna	— ornithopodioides	Asplenium septentrionale.
Gentiana amarella	— argentea	— scabrum	
	Spiræa Filipendula		

1463. *The trees that are aboriginal natives of Britain* are the Oak (two species); the Elm (five species); the Beech, the Ash, the Maple, Sycamore, Hornbeam, Lime (three species, according to Smith); the Spanish Chestnut (?); the Alder, Birch, Poplar, (four species); and the Scotch Fir: to which may be added the Mountain Ash, which in some parts of Scotland attains to a great size. Of these, then, the Oak, the Beech, Birch, and Scotch Fir live in society, —

“ In grouping beauty rise the loftiest trees,
Secure in friendship from the blighting breeze; ” —

forming vast forests, almost to the exclusion of other trees. The finest forests of Oak and Beech are unquestionably to be seen in the southern parts of England; the latter flourishing, to an extraordinary degree, in the chalk and deep clay soils of Sussex and some of the neighbouring counties. In Scotland, the oak, though there may be some exceptions, generally forms copse woods, and is mostly confined to the valleys. Its northern limit is scarcely within the British dominions. It extends to lat. 60° on the continent in Russia, and 64° in Norway; and if in Scotland oaks are not found in the extreme north, it is rather owing to want of shelter and of suitable soil, than to any other circumstance.

1464. *The Pine (Pinus sylvestris, fig. 114.)* constitutes noble forests among the mountainous districts of

SCOTCH FIR.

North Britain, filling the valleys, and ascending, probably, to the height of 2500 feet upon the hills, among the northern Grampians, especially in the districts of Braemar, Glenmore, and Rothiemurcus; and exhibiting individual specimens of such size and beauty as no one can form an idea of, who has not seen this tree in its native situations. About 20 years ago, the greater part of the noble forest of Glenmore, belonging to his Grace the Duke of Gordon, was cut down, and floated to the sea at Speymouth; where several ships were built of the excellent timber which it afforded. One individual was then felled, which afforded a plank, which we have seen at Fochabers: it is 5½ feet in diameter, and free from every kind of imperfection.

1465. *Of the fruit trees* which are successfully cultivated in the open air, the number is limited. In the south, exclusively, or, perhaps, as far as the centre of the kingdom, under favourable circumstances, the Vine, the Fig, the Quince, the Mulberry, Chestnut, Walnut, and Medlar may be advantageously planted. The Apple, Pear, the Plum of various kinds,

the Peach, Nectarine, and Apricot; all, according to soil, exposure, and other local circumstances, ripen their fruit in the open air, if afforded the protection of a wall, as high north as Inverness, and some of the most hardy ones much higher: but the want of sun must ever be a hinderance to the thorough perfecting of good fruit in the north of Scotland.

1466. *Of the various kinds of Corn*, which are used as food for man or cattle, Wheat, Barley, Bere, Bigg, Oats, and Rye are the universal crops; and these all succeed in situations not too much elevated above the level of the sea, as far to the northward as Inverness, beyond which the wheat becomes a very uncertain crop; and even considerably south of Inverness, to the north of the Forth and Clyde, in lat. 56°, the cultivation of wheat is almost wholly confined to the eastern side of the country, the west being the district for pasture.

1467. *In regard to the height* at which certain plants will grow above the level of the sea, the southern and midland parts of Great Britain do not contain mountains upon a sufficiently lofty scale to render their investigation particularly interesting. The northern parts of England possess mountains of considerable elevation, upwards of 3000 feet; and it has fortunately happened that Mr. Winch's "Essay on the Geographical Distribution of Plants throughout the Counties of Northumberland, Cumberland, and Durham," of which the lat. 55° may be considered the medium, embraces a very great proportion of this very country, which, from its situation, may, in point of climate, be considered as intermediate between the more northern and southern floras of Great Britain; and though we cannot devote the room that would be necessary to introducing the whole of his remarks upon the humble and less known vegetables, yet we gladly select from the writings of so accurate an observer what concerns the more valuable and more striking vegetable productions.

1468. *The Oak*, in lat. 55°, attains a large size in the valleys; it ascends the hills, but gradually becomes of stunted growth in Weardale and Teesdale, to the elevation of 1600 and 1700 feet.

1469. *The Common Elm (Ulmus campestris)* is not indigenous north of the Tees;

its place being taken by the Wych Elm (*U. montana*), which skirts the mountains at a height of 2000 feet.

1470. *The Beech and Aspen* are truly natives, flourishing beautifully in the low sheltered spots, but not climbing the hills to equal heights with the oak. The White and Black Poplars (*Populus alba* and *nigra*) are doubtful natives of the north of England, as of Scotland; though the White Poplar is remarkable for withstanding the north-easterly winds, which are so destructive to vegetation in the counties of Northumberland and Durham. The Lime (*Tilia europæa*), the Chestnut (*Castanea vesca*), and the Hornbeam (*Carpinus Betulus*), stand in the same predicament.

1471. *Holly trees* are among the chief ornaments of the woods in Durham, Northumberland, and Cumberland, as is the Yew (*Taxus baccata*). The Birch (*Betula alba*) equals in size the birches of Norway and Sweden; but is not found on the mountains at a greater elevation than the Sycamore (*Acer Pseudo-platanus*), which in the subalpine regions seems to be as vigorous, and to attain as great a size as it does near the sea-coast. The Mountain Ash (*Pyrus aucuparia*) is found on the hills; the White Beam (*Pyrus Aria*) may be traced from the High-Force of the river Tees to the coast; the Alder (*Alnus glutinosa*) and the Guelder Rose (*Viburnum Opulus*) accompany our streams; and the Hazel, Black Cherry (*Prunus Cerasus*), Bird Cherry (*Prunus Padus*), the Spindle-tree (*Euonymus europæus*), the Raspberry (*Rubus idæus*), and the common Elder (*Sambucus nigra*), are found in all the woods from the sea-shore to those situated on an elevation of 1600 feet: but the common Maple (*Acer campestre*) occurs only in the hedges, in some parts of the flat country.

1472. *The Ash tree* (*Fraxinus excelsior*), the White Thorn (*Mespilus Oxyacantha*), the Crab tree, or Wild Apple (*Pyrus Malus*), and Black Thorn (*Prunus spinosa*), abound throughout the district in question. The Bullare (*Prunus insititia*) is rare; and the Plum-tree (*Prunus domestica*), Pear (*Pyrus communis*), Red Currant (*Ribes rubrum*), the Berberry (*Berberis vulgaris*), and Gooseberry (*Ribes Grossularia*), though of frequent occurrence, appear not to be original natives of the soil. But the Rock Currant (*Ribes petræum*), the Acid Mountain Currant (*Ribes spicatum*), Alpine Currant (*Ribes alpinum*), Black Currant (*Ribes nigrum*), and Privet (*Ligustrum vulgare*), are indigenous, and not unfrequent.

1473. *On the elevated moors*, and even on the mountain of Crossfell, at an elevation of nearly 3000 feet, the roots and trunks of very large Pines (*Pinus sylvestris*) are seen protruding from the black peat moss: but the tree is no longer indigenous to the country; nor does the same tree now attain the size of the ancient Pine, though planted in similar moorland situations, though the young trees be protected, and even the plantations situated at a lower level.

1474. *The Furze* (*Ulex europæus*) attains to an elevation of 2000 feet in sequestered spots, accompanied by the Bramble. Juniper may be traced from the coast to the height of 1500 feet. The Cloudberry (*Rubus Chamæmorus*), the Bearberry (*Arbutus Uva ursi*), and Sand Willow (*Salix arenaria*), attain the same elevation; while the Dwarf Willow (*Salix herbacea*), but without its usual attendant the Reticulated Willow (*S. reticulata*), reaches to the tops of the loftiest mountains, upwards of 3000 feet above the level of the sea.

1475. *Coarse Grasses, Sedges, and Rushes* too often cover the wet moors with a scanty and almost useless vegetation. To the agriculturist the different Heaths are scarcely more acceptable; but they are unquestionably among the most beautiful of our native plants, and their abundance and the vast extent of ground which they clothe, give a peculiar character to very many parts of Great Britain, especially in the North. In the districts in question, the common Heather (*Calluna vulgaris*), the Fir-leaved Heath (*Erica cinerea*), and the Cross-leaved Heath (*Erica Tetralix*), the latter, however, less fragrant, and preferring moist situations; these flourish in various situations, from 1000 to 3000 feet above the level of the sea, but never in calcareous soil; which circumstance, Mr. Winch observes, occasions the striking difference between the heaths of Durham and Northumberland, and the Yorkshire Wolds as they are called, where the substratum is chalk.

1476. *The most considerable elevation* to which the cultivation of wheat extends in the north of England does not exceed 1000 feet above the level of the sea. Oats grow at nearly double that height; but in unfavourable years the sheaves may often be seen standing among the snow, which not uncommonly covers the tops of the mountains in October, and is never later in falling than the middle of November. The limits of Barley and Rye are between those of wheat and oats; but Bigg, a more hardy kind of grain than either of the former, is no longer cultivated. Turnips, though of small size, and Potatoes, grow at the same height as Oats. On the soil of the moors being ploughed for the first time, and lime applied, White Clover (*Trifolium repens*) comes up in abundance; and the same circumstance is noticed by Mr. Pursh to occur in North America when the woods are cleared away, and the ground first broken up.

1477. *Observations, similar to those we have now exhibited*, in a suitable part of Scotland were still a desideratum; and we have been fortunate enough, through the medium of Dr. Alexander Murray of Aberdeen, to obtain them from the Rev. James Farquharson, minister of Alford, Aberdeenshire; a gentleman, as his remarks will show, of much scientific knowledge, and great and patient research. It is to be hoped he may be induced to continue his investigations on these interesting subjects: and this may encourage others possessed of similar acquirements, and equal facilities, in different parts of Scotland, to collect a series of observations, which would be of the greatest service in forming a complete system of the *Vegetable Geography* of these islands. With this communication of Mr. Farquharson, which

we shall give in his own words, we shall close our remarks, already perhaps too much extended for the nature of this work, on *British Botany*.

1478. "The district," Mr. Farquharson writes, "to which the following observations chiefly refer, is near the middle of Aberdeenshire, about lat. $57^{\circ} 15'$; and may be termed a table land, elevated 400 to 600 feet above the sea, studded with many irregular ridges and groups of mountains, of different elevations, up to 1800 feet from the level of the sea. The substratum is every where what is named primitive rock, granite, gneiss, and micaceous slate; the soil generally a friable, dark, vegetable mould, passing in some places into a lighter-coloured and more tenacious clay, and all containing many fragments of the primitive rock. A debris of clay and broken stones sometimes intervenes between the rock and the soil; but the many operations of road-making, draining, enclosing, and quarrying, which have of late years been performed within the district, show that this debris is not very extensive nor very deep, excepting at the edges of some of the more precipitous elevations. A valley in this district, about eight miles long and seven broad, nearly rectangular, and surrounded by ridges of the mountains, has furnished most of the phenomena here stated. The mean temperature of the air has not been determined; but two fine perennial springs, at an elevation of 500 feet above the level of the sea, on the 20th of November, 1828, gave 47° of Fahrenheit.

1479. *List of plants*, stating in feet the elevation above the sea which they reach, in the district of Alford, Aberdeenshire; and beyond which they do not grow, or cannot be cultivated successfully. Latitude $57^{\circ} 15'$; 25 miles inland:—

"1. 400 feet. Wheat. This grain has been repeatedly cultivated in the valley, from this height up to 600 or 650 feet, within the last thirty years, by persons from the south country, well acquainted with its mode of culture, and on a large scale; but the result, owing to its frequently failing to ripen well, has not justified the extension, or even the continuance, of its growth here; and it is now rarely attempted. When it did ripen, in favourable seasons, the crop was abundant. It succeeds tolerably well nearer to the coast, about 150 feet lower.

"2. 400 feet. Barley (*Hordeum distichum*). This has often been attempted, in place of the Bigg (*Hordeum hexastichum*).^{*} It proved late, and frequently failed.

"An early variety, named Corsican Barley, succeeded admirably in situations as elevated as the Bigg, over which it had the great advantage of not being liable to lodge; but its culture has been discontinued, owing to the impolitic regulations of the Excise, which prohibit the malting of Bigg and Barley on the same premises; and as the maltsters generally use Bigg, our common grain, they could not, owing to this regulation, purchase Barley.

"3. 950 feet. Bigg succeeds quite well up to this height, and often ripens in the more inland districts about 100 feet higher, where oats frequently fail.

"4. 950 feet. Oats fail so frequently to perfect their grain higher than this, as to render their cultivation inexpedient at a greater elevation; and as they form the most important crop of our known rotations of cropping, no other kind is attempted at more elevated districts.

115

A, TWO-RANKED BARLEY.
B, FOUR-RANKED BARLEY.
C, SIX-RANKED BARLEY.

"5. 950 feet. *Avena strigosa* follows the cultivation of both Bigg and Oats to this height; and as its increase is greater in proportion than theirs, it might probably succeed a good deal higher.

"N.B. The introduction of comparatively early varieties, as the Early Angus and Hardy Red Oats, which has already greatly benefited the farmer in

^{*} I am not even sure that our Bigg is the *Hordeum hexastichum*. We have another kind of barley, called Packman-rich, which is as early as the Bigg, and more evidently distinctly six-rowed in the ear; the grains being also more closely packed in the rachis. It is seldom sown, being not quite so productive as the common Bigg. I suspect it may be the true *Hordeum hexastichum*. The former is doubtless the *Hordeum vulgare* of Linnæus, or four-ranked barley (fig. 115. b), the latter the *Hordeum hexastichum* Linn., or six-ranked barley (c). In both there are six rows or ranks of seeds; but in the *Hordeum vulgare* (*Hordeum hexastichum* of Gray's *British Flora*), two opposite pairs of rows have the seeds more erect, imbricated, and compressed, appearing to constitute but two single rows; the other two or lateral rows of seeds are much more prominent. In *Hordeum hexastichum* the seeds arrange themselves in six distinct and prominent rows. These are the two most hardy kinds, and such as are generally cultivated in the northern and mountainous regions. In the south of Scotland, and in England generally, the *Hordeum distichum* of Linnæus, common or two-ranked barley (a), is cultivated. In this kind the two opposite double rows are abortive, and nothing but small empty bushels appear instead of seeds. The name of Bigg, or Bere, or Bear, is usually given to the four-sided barley, and that of six-sided Bigg or Bere, and Barley Bigg, to six-sided; but in common language they have often no distinguishing appellation. — Ed.

this valley, will, perhaps, enable him to push his cultivation a little higher; where, at many points, there is yet good soil untouched.

" 6. 950 feet. White Norfolk Pea. I introduced these in the lower part of the valley, about seven years ago, where they have always done well; and two years since I gave some for sowing in some of the highest cultivated lands of the district, where they have been equally successful, ripening before the Bigg. Grey Peas so often fail to ripen here, that they are seldom sown.

" 7. 600 feet. English Winter Tares (*Vicia sativa*). I began to plant these eight years ago, as a spring crop, and they have answered admirably in damp land. I have always been enabled from a portion of the crop to secure seed for a succeeding one. When sown in May they are heaviest to be cut from September to November.

" 8. 950 feet. Potatoes succeed with the oats here; but often fail to come to perfection in the Highland glens, even a very little more elevated than this.

" 9. 950 feet. Turnips become a valuable crop. The Red and White varieties are only for autumn use, as they often perish in winter; but we have a hardy Yellow variety, which I have never seen materially injured by cold, except in the unusually severe frosts of 1813 and 1814. Rutabaga is not planted; and as its produce is of much less weight, and as we have this valuable yellow sort, we do not require any which is more hardy.

" 10. 950 feet. Rye Grass (*Lolium perenne*).

" 11. 950 feet. Red Clover (*Trifolium pratense*).

" 12. 950 feet. White Clover (*Trifolium repens*).

" These three plants form our usual sown-grass fields for hay and pasture, and they answer well at this height. The last is a native, even higher. Thus we see that, to the most elevated points where oats, the principal crop, ripen, the cultivator gets up along with them all the plants necessary for a judicious rotation of crops: Turnips, Bigg, Rye-grass, and the Red and White Clovers.

" 13. 450 feet. Sainfoin (*Hedysarum Onobrychis*). I made an experiment on a small scale, three years ago, to introduce this on a piece of very dry, sandy, but rich and well-limed land, at this altitude: the plants came up freely, and many of them were remaining on the second year, but in the third year they had almost entirely disappeared, none having ever flowered.

" 14. 400 feet. Field Bean (*Vicia Faba*) does not ripen: a broad Spanish bean comes to perfection in gardens often.

" 15. 450 feet. Jerusalem Artichoke (*Helianthus tuberosus*) never flowers, but is propagated by tubers.

" 16. 450 feet. The Squash, recently introduced, named Vegetable Marrow (*Cucurbita Succado*, in Loudon's *Encyclopædia of Gardening*), perfects its seeds when sown under a hand-glass, till the second leaf expands, and then it may bear transplantation into the open ground.

" 17. 670 feet. Nasturtium (*Tropæolum majus*) has sometimes perfect seeds.

" 18. 950 feet. Flax (*Linum usitatissimum*) grows as high up as the Bigg.

" 19. 650 feet. Caraway-seed (*Carum Carui*) propagates itself by seed on a piece of enclosed grass.

" N. B. Many plants, as *Papaverum somniferum*, *Verbascum Thapsus*, *Dipsacus fullo-nium*, *Cheiranthus Cheiri*, *Dianthus barbatus*, not being natives of this part of the kingdom, yet propagate themselves by seed, without any attention being paid to sowing them, on the cultivated ground of a garden at 450 feet from the level of the sea: and at New, in Strath-dow, about 800 feet high, a great variety of kitchen-garden herbs come to perfection in the open air, such as Strawberries, Beet, Carrot, Onions, Chives, Leeks, Parsley, Cresses, Let-tuces, Radish, &c. The Cabbages and Greens are good at all the highest points to which cultivation is extended.

Trees and Shrubs.

" 20. 700 feet. Oak (*Quercus Robur*).^{*} Half-rotten trunks of this tree, of only moderate dimensions, occa-sionally dug out of the ground (of which I have seen several), prove this tree to have been, recently, a native of this district; and a tradition, which may be relied on, points out the spots which furnished the timber of the old church at Forbes, situated within the valley, the only building constructed of oak in the neighbourhood. The native Oaks have all disappeared; unless a solitary small tree, remote from any others of equal age, and growing amidst an unprotected Hazel copse, within a mile of the above-mentioned spot, and on similar ground, may be considered as such. There are a great many planted Oaks in the valley, some of them at the above ele-vation, but their autumnal shoots (this tree sending out two shoots in a season) are generally killed in the succeeding winter.

" 21. 750 feet. Beech (*Fagus sylvatica*) becomes a very fine tree in the lower part of the valley, but a few reaching this elevation are miserably stunted.

" 22. 500 feet. Hazel (*Corylus Avellana*), is wild here, and ripens its nuts well: this cannot be considered as the farthest limit of its growth; but the progress of cultivation has probably exterminated it in higher spots.

" 23. 950 feet. Alder (*Alnus glutinosa*), in a natural state, skirts every where the streams in the low grounds: a few very small dwarf bushes of it are found in one place at this height.

" 24. 1050 feet. Scotch Fir (*Pinus sylvestris*) ceases to be of any value at a greater height, though it struggles a little farther still, in stunted mis-shapen bushes.

" 25. 1100 feet. White Birch (*Betula alba*) advances but a little farther than the Scotch Fir, as appears at one spot, where they were planted and have grown together.

^{*} Probably *Quercus sessiliflora* Smith.

"26. 1200 feet. Larch (*Pinus Larix*). This native of the Alps is now extensively planted, in all parts of the valley, with the greatest success; and at this height some extensive shrubberies, of eight or ten years' standing, mingled with Scotch Firs, appear in a prosperous state. One plantation has been carried as high as 1450 feet; but the Larches for 250 feet downwards are dwarf and sickly; and it appears likely that but few will exist long, beyond 1200 feet of altitude. The Larch was introduced here about sixty years ago; but being then deemed a delicate tree, none were tried on very high ground. The growth of the Larch is much more vigorous than that of the Scotch Fir; and being from the primitive regions of the Alps, the soil of Aberdeenshire proves very congenial to it, being chiefly primitive rock. The timber which it affords is strong and very durable. Sixteen years ago I had two gates made of Larch only forty years old; and although these have been constantly exposed ever since, the timber shows very little appearance of decay.

"27. 420 feet. Silver Fir (*Pinus Picea*). One plant of this native of the Pyrenees, the only one of any considerable age in the valley, has attained a large size, being 75 feet high, and containing 230 cubical feet of very healthy and growing timber.

"28. 800 feet. Hawthorn (*Mespilus Oxyacantha*) has, at New, at Strathdow, formed fine hedges at this elevation. In the valley, there are two fine solitary trees of it, at an altitude of 650 feet; a few good hedges are also seen in the lower grounds.

"29. 900 feet. Ash (*Fraxinus excelsior*) grows tolerably well at this height.

"30. 900 feet. Sycamore (*Acer Pseudo-platanus*).

"31. 500 feet. Elm (*Ulmus montana*) becomes here a fine tree: it has not been tried higher.

"N.B. *Tilia europæa*, *Populus alba* and *tremula*, *Salix alba*, *Æsculus Hippocastanum*, *Sambucus nigra*, *Carpinus Betulus*, *Cytisus Laburnum*, *Pyrus Aucuparia*, all thrive well in the lower districts of the valley, but have not here been planted nearly so high as the extreme limits of their growth. The *Populus balsamifera*, at 450 feet, appears sickly, and would not probably succeed any farther up.

"32. 800 feet. Cherries produced very fine and abundant crops, at New, in Strathdow.

"33. 800 feet. Apples are here a very uncertain crop; but at Castle Forbes, 500 feet high, they do not often fail. Auchintoul, the Ribston Pippin generally ripens well.

"34. 800 feet. Pears, the Jargonelle ripens here; but at 450 feet, the Auchin Pear seldom comes to perfection.

"35. 900 feet. Gooseberries. This valley is the region of most delicious gooseberries; and when our best kinds, especially the Red Walnut, are in season, we need not envy the fruits of the most favoured regions. I have heard, from good authority, that Bishop Forbes of Aberdeen, who died in 1635, had remarked, that gooseberries became more delicious as they approached the upper limit of their cultivation, and that the Scots, in his day, possessed the finest varieties of this fruit; and that at his own castle of Carse, about 750 feet high, he had them of a higher flavour than he knew them to have any where else. Gooseberry bushes cease to become productive near the limits of our highest cultivation.

"36. 800 feet. Raspberry (*Rubus Idæus*) is indigenous in the woods, at 650 feet.

"37. 1000 feet. Broom (*Spartium scoparium*) is found here in a stunted state, but bearing flowers.

"38. 850 feet. Whin or Furze (*Ulex europæus*). Several patches, at this elevation, seem to have no tendency to grow any higher up, although they spread laterally.

"39. 700 feet. Honeysuckle (*Lonicera Periclymenum*) will flower, if nailed to a wall.

"40. 600 feet. Evergreen Thorn (*Mespilus Pyracantha*), when attached to a wall, flowers in June, and ripens its dense branches of fine scarlet berries in October, which continue till it is again in blossom. It is one of our most ornamental shrubs.

"41. 600 feet. The Lilac (*Syringa vulgaris*) flowers here, but the inflorescence is always abortive.

"42. 450 feet. Evergreen oak (*Quercus Ilex*). Some years ago I obtained a few plants of this: they died down to the ground in winter; sending up new shoots from the root in spring, for two or three years, and then perished.

"43. 450 feet. Common osier (*Salix viminalis*) was given to me several years ago; but it does not thrive, dying very frequently in winter, especially the preceding year's shoots, and often indeed the whole plant.

"44. 450 feet. Berberry (*Berberis vulgaris*) ripens its fruit.

"45. 450 feet. Daphne Mezereum ripens its berries.

"46. 450 feet. The Hop (*Humulus Lupulus*) rarely produces any catkins.

"N.B. *Ligustrum vulgare*, *Cornus sanguinea*, and *Lonicera Xylosteum* blossom at 450 feet; but I have not seen them produce berries, except in the favourable season of 1827, succeeding the still warmer one of 1826. The *Ligustrum* and *Cornus* bore many berries on that year, and even the *Lonicera* had a few, all of which appeared to be fully ripe. *Artemisia Abrotanum* never flowers."

To some further queries which we addressed to Mr. Farquharson, respecting the influence of soil and situation, he obligingly communicated to us the following replies:—

"It is quite evident, from many indications, that the richness or poverty of the soil possesses considerable influence in extending or limiting the upper boundaries of the growth of all vegetables. In regard to the Herbaceous Plants and Gramineæ, the power of these circumstances becomes quite apparent in any field where a portion has been put into better order than the rest, by recent manuring, &c. In the manured part, the crops are much more luxuriant, and always somewhat earlier. This advantage would be again counteracted by a slightly increased elevation. Another condition of soil, its wetness or dryness, has much more effect in checking or extending the boundaries of these vegetables. It is only on dry lands that the different grains ripen at their respective highest elevations; and the retarding influence of a wet soil is so great as to make the crops in some of the lowest districts of the valley perhaps equally late with those in the highest. In regard to trees, it is apparent at many points in this country, that poverty of soil has prevented them from attaining their usual limit of altitude. The effect of a wet or dry soil varies upon trees, according to the habits of the different kinds, and cannot be defined.

"As to exposure, I have never been able to ascertain that this modifies the attainable elevation of any of the herbaceous or annual tribes.* Almost every variety of situation,

* "As the position, that exposure does not modify the attainable elevation of the herbaceous and annual tribes, may appear rather startling; it seems necessary, in support of it, to refer to several localities, where the most satisfactory proofs of it occur. And first, in respect of aspect. In the lower part of the valley, the three points where the earliest crops uniformly occur almost every season are, Tulloch, in the parish of Keig; Montgarry, in the parish of Tullynessle; and some north fields in the Gallowhill, in the parish of Alford. The first of these has a direct west aspect; the second, a direct south one; and the last has an aspect within one point of the north, on a steep descent. The earliness is owing to the dryness of the soil. Next in order to these, in point of earliness, are some fields on Upper Auchintoul, having an aspect a little to the south of east. In the higher cultivated lands, the south-lying fields of Upper Balfour, in the parish of Forbes; the east-lying fields of Tiverchindy; and the west-lying fields, on the opposite side of the dingle at the same place, in the parish of Alford; and the fields near the top of the hill at Campfield, parish of Lun-

both of aspect and shelter, occurs within this valley at all elevations ; and it does not appear that in sheltered grounds the crops are earlier than on those which are open, or the contrary ; or that the produce of fields having a northerly aspect is earlier or later than that of ground lying to the south. The circumstance of elevation, with respect to these plants, quite counterbalances the conditions both of aspect and shelter. It is true, indeed, that in the spring the vegetation is often much earlier in fields lying open to the south, than those which face the north ; and pastures which have the former exposure are valuable on account of their early herbage. But for the final maturing of the ordinary crops, the disadvantages attendant on a north-lying field is compensated when the sun reaches the northern tropic ; and these situations then enjoy all the benefit of his morning and especially his evening rays, which is generally considerable. In exact conformity with this view, it does not appear that farther inland, where the glens are narrower, and more protected by high mountains, the grain ripens at higher elevations than here. Certainly cultivated spots are found somewhat higher than any in Alford : but then the culture is not conducted solely with a view to the grain, but chiefly for the winter fodder necessary to support numerous herds of small cattle, which feed on the extensive mountain pastures in summer ; and it is a common saying among persons possessed of these lofty spots, that if their grain ripens once in three years, it is all that they expect.

“ On Trees and Shrubs, however, which are of loftier growth than the annual and herbaceous plants, and have to endure the severity of winter storms, the exposure has a most powerful influence. The numerous and extensive plantations in this valley furnish the most decisive evidence on this point. Many stations occur where the Scotch Fir, for instance, is dwarfish, and even killed, much below its natural limit ; owing evidently to an unfavourable exposure, and not to any deficiency or unfitness of the soil ; for in some of these places, corn crops of good growth are mingled with the plantations, or pass along the sides of them, and the trees have succeeded quite well in spots that are incidentally sheltered. It is, indeed, from its circumstances of shelter, and not of aspect, that exposure exercises such a powerful influence ; for if the trees, planted in ground having a westerly or north-westerly aspect generally suffer most, and are most limited in their elevations, it is because our severest storms come from the west and north-west, and the trees so situated are exposed to their full violence. It may be concluded, therefore, that if we could command more shelter, trees, at least our native ones, would succeed at higher points than they here reach ; and accordingly, I have been given to understand that at Braemar, in the upper part of this country, which is sheltered by the loftiest and most extensive masses of mountains in all Scotland, attaining a height of 3000 and 4000 feet and upwards, the Scotch Fir and White Birch grow at a much higher elevation than any I have named. Of this, however, I cannot give the exact particulars, but I believe the general fact.

“ I can say nothing, from personal knowledge, of the different circumstances attending the extension of plants on the east and west coasts of Scotland ; and I would not, therefore, have referred to the subject, except to bring forward a remark made in a work, not professedly scientific, and therefore, perhaps, liable to be overlooked : it is in Dr. Macculloch's interesting *Letters from the Highlands and Western Islands of Scotland*. He states the fact, that grain ripens better in the outer Hebrides than in the islands nearer the mainland, or on the west coast of the mainland itself ; and the cause which he assigns for this striking circumstance is, that in these outer islands there is not sufficient elevation or continuity of land to lift up the atmosphere, and thus arrest and condense the vapours with which our prevailing westerly winds come loaded from the Atlantic. These islands, therefore, often, in summer, enjoy clear weather, when the inner islands and mountains are deluged with rain, or obscured by a heavy cloud.”

SUBJECT. 3. *Zoology of Great Britain.*

1480. *The history of our native animals* is naturally more interesting, to the generality of readers, than of such as do not come under their own immediate observation ; while to be ignorant of the names and properties of beings which every where surround us, is neither a proof of wisdom nor of a well-informed mind. Those who take an interest in the works of nature begin by examining objects immediately within their reach ; and as few can extend their enquiries beyond such limits, the productions of every country will be best known, in proportion to the taste for such enquiries among its inhabitants.

1481. *The zoology of Britain* was first investigated by Ray, the great father of natural history, since the revival of learning after the darkness of the middle ages. This wonderful man must be also considered the true founder of natural history in Britain ; and by his instruction and assistance, the name of his friend and

phanan, having every variety of aspect ; all these, at least the dry parts of them, ripen their crops at the same time, at upwards of 900 feet above the level of the sea. Secondly, in respect of shelter. The finely sheltered fields about Haughton, in the parish of Alford, appear to have no advantage, in point of earliness, over the entirely open grounds of the farm of Muckleindovie, in the same parish ; although many of them are equally dry with the latter ; these are in the lower part of the valley : and about 300 feet higher, the well-sheltered and dry fields of Craigievan, in the parish of Leochhill, are no earlier than many quite open fields, at the same elevation, in the immediate neighbourhood. In the spring months, however, the pastures of the sheltered, and especially the south-lying fields, possess the superiority mentioned in the text.”

patron Sir Francis Willoughby shares a portion of the same immortal fame. But our native zoology, even at that period, engaged the attention of another labourer. The name of Lister must therefore be honoured, in conjunction with that of Ray, as having been the first who undertook to investigate the extensive order of molluscous animals: these he arranged with such an admirable perception of natural affinities, considering the period in which he wrote, that we know not which to admire most, the acuteness of his views, or the magnitude of his undertaking. It would have been well for the fame of Linnæus, had he paid more consideration to the writings of these philosophic observers, one of whom has justly been called his master; while the other was no less his superior in a correct knowledge of the testaceous animals. To these we must add the name of Ellis, whose work on Corallines, printed in 1755, has continued until the present day to be the most elaborate and valuable publication on this class of animals that has yet appeared: a long interval then succeeded, during which naturalists employed themselves merely in describing species, and in illustrating the Linnæan nomenclature. The only writer, of this period, whose works are now of importance, was George Edwards, whose *Natural History of Birds*, pretending to nothing more than plain and accurate descriptions, free from all scientific arrangement, has become, from that very cause, of great and general service. A return to a more accurate observation of natural groups first appeared in the *Lepidoptera Britannica* of Haworth, and in the elaborate work upon our native bees by Mr. Kirby; from these we may date the revival of natural history in Britain, from a vocabulary of words, to an intellectual science. Although not absolutely connected with our more immediate purpose, we deem this rapid glance over the history of the science in Britain will not be an unwelcome preface to the following remarks.

1482. *The zoology of the United Empire* might be treated of under the three kingdoms of which it is composed; were our materials sufficiently ample to mark the peculiarities of each. But it unfortunately happens, that although every year witnesses an accession of new species enrolled in the annals of our native fauna, no attempt has yet been made to generalise these discoveries, with reference to the geographic range of groups or species. Local catalogues of the animals found in a few counties have, indeed, been drawn up; but these, however valuable in themselves, are too scanty to allow of more than a partial insight into the general subject. The zoology of Ireland has been sadly neglected, and we are still without a *Fauna Scotica*. Thus embarrassed, we must consider the natural history of Britain in the aggregate; noticing such species as more particularly belong to the northern and the southern extremities.

1483. *Of Quadrupeds*, the most recent catalogue contains sixty living species, including the whale tribe; besides those which progressive civilisation, and the effects of the chase, have now extirpated from our islands. Nine species of Bats have been detected, four of which have as yet been found only in the southern and western counties: two belong to the division of horse-shoe bats, so named, from their nostrils being furnished with a complicated membrane, like a horse-shoe; an appendage which is probably intended to act as a sucker to assist the animal in retaining its prey. Another, the *Vespertilio murinus*, or common bat, as we are informed by White, has been so far tamed as to take flies out of its master's hand, carefully throwing aside the wings. Our woods and heaths still shelter the Hedgehog (*fig. 116.*),

116

HEDGEHOG.

a harmless and a most useful animal in destroying snails, slugs, and worms; but persecuted by the vulgar for a long list of imaginary and nonsensical properties. These prejudices have been extended to the Mole, whose little hillocks form the best top-dressing, as a sensible farmer once assured us, to poor lands, that can possibly be given: their soft fur has long been mixed with that of the Beaver, in the making of hats. Allied to the Mole, in general conformation, are the Shrew Mice, of which two species are natives, the common and the Water Shrew (*Sorex araneus* and *fodiens*): both these appear to be widely distributed. Of true Mice we

possess three distinct sorts: the Common or House Mouse, the Field Mouse, and the Harvest Mouse; the latter being as destructive to the farmer as the first is to the housewife. The Brown and the Black Rat infest our dwellings, and are equally injurious: the latter is known by the tail being longer than the body; whereas, in the Brown Rat, both these parts are equal. The pretty little Dormouse (*Myoxus avellanarius*) is a general favourite, and, like the Squirrel and Jerboa, eats its food in an erect attitude, sitting on its haunches, and using its forefeet as hands. The Water Rat and Short-tailed Mouse of Pennant (now placed in the genus *Arvicola*) occur in England: but the former is stated not to have been found in the northern islands; the latter is a most destructive little animal in gardens, where it grubs up seeds, particularly peas, just after they have begun to germinate. A few years back, the short-tailed mouse suddenly appeared in immense numbers in the New Forest, and notwithstanding every artifice employed to stop their ravages, they destroyed many thousands of young trees, and devastated whole acres of young plantations.

1484. *The Badger* was formerly a much more common animal in Britain than at present. It is a nocturnal feeder, sleeping in its hole during the day, yet, when attacked, is remarkably quick in its motions, and successful in its defence. If undisturbed, it is harmless and inoffensive, chiefly subsisting upon vegetables, although it will likewise devour frogs and slugs. It is stated to inhabit Sweden, although it does not appear to be known in the north of Scotland. The *Otter* has likewise become much less frequent of late years; it was formerly considered as a beast of chase, as our old game books mention otter hounds as particularly trained for hunting this animal. It feeds entirely upon fish, which it dives after with great celerity; and, unless pressed by extreme hunger, invariably leaves the tail extremity untouched. The legs are very short; and the toes being connected together by a membrane, gives to the animal the power of swimming very rapidly.

1485. *Our rapacious or carnivorous quadrupeds* are very few, and from their small size too insignificant to inflict much personal injury upon man. The *Bear* and the *Wolf* have long been extinct in Britain, and the *Fox* might possibly have shared the same fate, had it

not been preserved as a beast of the chase since the extirpation of more formidable game. Pennant mentions three varieties of this animal found in Wales and other mountainous parts of Britain: —1. The *Milgri*, or Greyhound Fox, is the largest, tallest, and boldest, and is distinguished by a white tag or tip to the tail. 2. The Mastiff Fox, which is less, but more strongly built. 3. The *Curgi*, or Cur Fox, of a still smaller size, and having the tip of the tail black. (*Brit. Zool.* i. 87.) The varieties do not appear, however, to have fallen under the actual observation of subsequent naturalists, either British or continental.

1486. The *Ferret* tribe comprehends the Polecat, Weasel, Stoat or Ermine, the Common Marten, and the Pine Marten.

1487. The Polecat (*Putorius vulgaris* Cuv.), called also the Fitchet, Fitchew, or Fomart, measures, with the tail, about twenty-three inches. Its fetid smell is proverbial. Although included in the list of British quadrupeds, it appears, according to Strabo, to have been imported from the north of Africa. Like all its congeners,

117

STOAT.

its habits are sanguinary; for it will destroy and suck the blood of many victims, before it attempts to carry off their bodies. The well-known Ferret is considered only a variety of this species. The Weasel is much smaller, and although repulsive from its odour, is yet an elegant-shaped animal. It feeds on mice and small birds, but will occasionally attack animals of a much larger size. Few persons suspect that the skins they see nailed against farm out-houses frequently belong to an animal whose fur, in another state, forms a most elegant and expensive ornament to female dress. This animal, despised in one state, and valued in another, is the Stoat (*fig. 117.*), the pest of the farmer, and the destroyer of his poultry. In the temperate and southern parts of Europe, its fur is yellowish-brown above, and pale yellow beneath; yet so soon as its geographic range enters on the more northern countries, as Russia, Norway, and Siberia, these colours vanish, leaving the fur of a pure white in every part but the tail, which is tipped with deep black; and in this state the skin is called ermine. In Scotland the animal, during winter, is frequently found in an intermediate stage of summer and winter clothing. Although small, it will attack large rats, and has been known to pursue a young hare by the scent.

118

PINE MARTEN.

1488. The Common Beech or Marten (*M. Fagorum* Ray) seems to prefer dwelling near habitations, choosing the shelter of out-houses and farm-buildings, as convenient retreats for carrying on its depredations among poultry, of which it is a great devourer; it also breeds occasionally in the hollows of trees. 1489. The Pine Marten (*M. Abietum* Ray, *fig. 118.*) is rather larger, and is further distinguished from the last in having the throat and breast yellow, instead of white. It is wild and solitary; shunning mankind; and only dwells in thick woods and forests, principally those composed of pines. It climbs with great facility; preys upon birds and their eggs, and also upon squirrels; the female generally making use of the nest of one of her victims for the rearing of her own young. The skin of this is much more prized than that of the common Marten, and appears to have been formerly, at least in Scotland, a lucrative article of commerce.

1490. The *Wild Cat* closes our list of these small but ferocious indigenous animals. Its manners are similar to those of the lynx, and Mr. Pennant justly calls it the British tiger. In its savage state it appears to be much larger than the ordinary domestic cat; and the teeth and claws, for the size of the animal, are tremendous. It is still found, although rarely, in the mountainous and woody parts of Great Britain, and some few years ago we saw a very fine skin of one that had been killed among the mountains of Westmoreland, near Windermere. Formerly they appear to have been much more numerous, and to have been considered a beast of chase. The best authorities agree in considering this species, common to the forests of Europe, as the origin of our domestic breed, the usual varieties of which are well known. Another, which seems more peculiar to Cornwall, has been noticed by Dr. Leach: it is without any visible tail, and is stated to be an hereditary variety. (*Cuv.* ii. 489.)

1491. To enumerate the varieties of the *Dog* now domesticated in Britain would be tedious, particularly after the luminous manner in which this subject has been treated by Pennant (*Brit. Zool.* i. 70.). Britain has been famous for her dogs from remote antiquity. Our mastiffs were held in such estimation by the Romans, that their emperors appointed an officer in this island, with the name of *Procurator Cynegii*, whose sole business was to breed and transmit from hence such as would prove equal to the ferocious combats of the amphitheatre. Strabo also mentions that the mastiffs of Britain were in great repute, being trained for war, and used by the Gauls in their battles.

1492. The *Bloodhound*, during the troubled periods of English history, was in high estimation, and much used to track the footsteps of robbers and marauders; but the breed is now extinct. A remarkable variety of the Greyhound, more peculiar to Ireland (hence called the Irish Greyhound or Wolf Dog), is nearly lost, a few couples alone having been preserved in one of the parks in that island. The Terrier is the best house guard; while the Shepherd, the Water, and the Newfoundland dogs are probably the most sagacious.

1493. Of *ruminating animals* now existing with us in a state of nature, there are but three; the Stag or Red Deer, the Fallow Deer, and the Roebuck. It would appear, however, that the first two are not indigenous to our islands. Mr. Pennant writes — "We have two varieties of fallow deer, which are said to be of foreign origin: these were introduced by King James I. out of Norway, which he visited for his intended bride, Anne of Denmark. He first brought some into Scotland, and from thence transported them to his chaces of

Enfield and Epping, to be near his palace of Theobald's." The only memorial of this palace is probably preserved in the name of Theobald's Road. M. Cuvier, indeed, expresses a doubt whether the stag was originally European; but Major Hamilton Smith, with much better reason, considers the Fallow Deer (*Cervus Dama*) as indigenous to Europe; adding, that it is still found wild from Sweden to Gibraltar, and from Ireland to Constantinople. The Stag (*Cervus Elaphus*) seems to be unquestioned as an indigenous species; and although the wild breed is yearly diminishing in numbers, it is still found in Gloucestershire, the north-west part of Devon, and in some of the remote districts of Scotland. Pennant, by some unaccountable mistake, has placed the Stag and the Fallow Deer as varieties of one species.

1494. The Roebuck (*Cervus capreolus* Ham. Smith) is much less than the two preceding, and is, indeed, the smallest of European deer. It is remarkably graceful and active, habitually preferring the sides of elevated woods or forests. As he leaves a strong scent, nature has given him peculiar sagacity to perplex his pursuers: he begins, after a forward dash, by doubling over his track, to mislead the hounds, and then by some great bounds he springs forward to a cover, where he lies down to let the chase pass. The roebuck is now become very scarce in Britain, and was equally so in Scotland, but we are told it has reappeared of late years in Fifeshire, in consequence of the increased plantations. (*Brit. An.* p. 26.)

1495. The Ox is the only remaining animal of this order which claims a place among our indigenous quadrupeds. We have before observed, that in remote ages, a gigantic race of oxen was numerous throughout Europe; and that, although now extinct, there is reason to believe that the colossal species mentioned by Cæsar, as existing in his time, was of this race, now only known by its fossil bones. These remains lay scattered through the whole of temperate Europe, in the same strata with the lost species of Elephant; but that the race was preserved to a much later period is proved by similar bones occurring in more recent formations, as in peat mosses, drained lakes, marshes, and beds of sand. The wild races, of inferior size, belonging to this species, may probably, as Major Smith observes, even now exist in Asia. However this may be, it appears certain that the real Urus was found wild in the Vosges mountains, and in the forests of Ardennes and Germany; while its existence in England is incontestably proved by Fitz-Stephen, who speaks of the *Uri silvestres*, which in his time (that is, about 1150) infested the great forests — round London!

1496. The only existing breed of wild oxen now known, is the white Urus, or *Urus scoticus* of Ham. Smith.

119

WILD SCOTTISH OX.

Its skull agrees with the fossil breed in being "square from the orbits to the occipital crest, somewhat hollow at the forehead, and the horns showing a peculiar rise from their root, at the side of the above crest, upwards, and then bending outwards, then forward and inward: no domestic race shows this turn." The true Urus was further distinguished by a mane, which is still observed about two inches long, in old bulls of the Scottish race (*fig. 119*). When this breed was exterminated from the open forests is not known; but it was confined to parks long before the Reformation. The colour is entirely white, with the muzzle wholly black. Their manners are singular: upon perceiving a stranger, they gallop wildly in a circle round him, stop and gaze, toss their heads, and show signs of defiance; this is repeated several times, each circle being made smaller, till they approach sufficiently near to make an effective charge. The cows conceal their young eight or ten days: and when one of the herd is wounded or enfeebled, the others gore it to death. The breed is still preserved at Chillingham Castle, near Berwick-upon-Tweed, Wollaston in Nottingham, Gisburne in Craven, Limehall in Cheshire, and at Chartley in Staffordshire.

1497. The domestic Ox (*Bos Taurus*), considered by some as a variety, and by others as a distinct species from the last, is supposed by Hamilton Smith to have been first domesticated by the Caucasian nations of western Asia. It is stated to have fourteen ribs, whereas those of the *B. Urus* are but twelve; a distinction

sufficiently important to sanction the belief of a specific difference. Whether or not this parent of our domestic races ever existed in these islands in a state of nature, is very doubtful. The various breeds for which Britain has long been justly celebrated will be noticed under the head of domestic animals.

1498. The marine and cetaceous mammalia are few, and are not very generally dispersed. Two species of Seal have been noticed by Pennant. The *Manatus borealis*, or Sea Cow, has only once been found on the northern coasts of Scotland; and the Walrus, at remote intervals, has been recorded as a visiter to our seas. The Piked Whales (*Balænoptera musculus* and *boops*), the Razor-back Whale, and several others of the great northern cetacea, wander near the Hebrides and Orkney islands, and occasionally visit the shores of Northumberland and Yorkshire. The Porpoise and the Grampus have a wider range, and large shoals roam unmolested near all our coasts. There can be no doubt that whales, of several species, were much more common in the northern seas of Britain formerly, than they are at present; but the persecution they have suffered, from the establishment of our fisheries, has long since driven them to the polar regions.

1499. Exterminated native animals. In every country the increase of civilisation and agriculture is marked by the progressive diminution and final extirpation of the larger quadrupeds, particularly of such as are injurious to man. Among those which history clearly informs us were once living in Britain, the most remarkable are the Bear, the Wolf, the Beaver, and the wild Boar. To the writings of Pennant and Hamilton Smith we are indebted for the following notes on these lost inhabitants of our forests.

1500. It appears that Bears, in the time of Plutarch, were transported from Britain to Rome, where they were much admired. Ancient Welsh manuscripts attest their existence in that country as beasts of chase; a fact further corroborated, says Pennant, by the frequent

name of Pennarth given to places in the principality: they appear to have been extinct in Britain long before Queen Elizabeth's time; but there is proof of the bear infesting Scotland in 1057.

1501. *Wolves.* It seems to have been a vulgar error that the wolf was extirpated in Britain by the salutary edicts of King Edgar, who accepted their tongues and heads as tribute, or as a commutation for certain crimes: for in the reign of Edward I. these animals had again increased to such a degree, that officers were appointed to promote their destruction, and lands were held by hunting and destroying them. Wolves infested Ireland many centuries after their extinction in England; some having been killed so late as 1710. In Scotland, the last on record was destroyed in 1680.

1502. *The Beaver* was still an inhabitant of the Welsh rivers in 1188, as is attested, according to Pennant, by Giraldus Cambrensis: but even at that remote period they must have considerably diminished, as the historian only mentions their being found on the river Teivi. Local names of other waters in the principality attest their existence in other places. Fossil remains of this species are stated to have been found in beds of marl, under peat moss, in Berkshire; and similar bones have occurred in Perthshire and Berwickshire.

1503. *The Wild Boar*, to which we are indebted for our domestic breeds of swine, must be reckoned among indigenous quadrupeds, although now extinct in Britain. Pennant quotes the laws of Howeldda, who permitted his grand huntsman during part of November and December to chase that animal. William the Conqueror punished, with barbaric cruelty, those who killed the Wild Boar, the Stag, and the Roebuck, by the loss of their eyes. Fitz-Stephen affirms that the vast forest, which in his time stood on the north side of London, was the retreat of Stags, Fallow Deer, Wild Boars, and Bulls. At a more recent period, Charles the First turned out Wild Boars in the New Forest; but they were destroyed during the civil wars.

1504. *Fossil quadrupeds.* The splendid discoveries that have resulted from the investigations of Dr. Buckland, Mantell, Conybeare, and other eminent geologists of our own country, have opened a native field of research, which, in Britain, had long been overlooked or neglected. Without entering into the question whether these fossil remains belong to animals which did or did not at some period inhabit the spots wherein their bones have been found, it is sufficient to confine ourselves to simple facts. The remains of the cave bear of Dr. Buckland occur in several of our caverns, and are sufficient to prove the living animal must have equalled a horse in size. The Kirkdale and Plymouth caves abound with the bones of an extinct hyæna, somewhat resembling in its osteology that now existing in South Africa; with these have been found the bones of a tiger, which must have been as large as the Bengal species. The tusks, teeth, and other fragments of an extinct species of elephant, totally different from those now in existence, have been detected in marl clay, &c. joined with those of two other gigantic quadrupeds, a rhinoceros and a hippopotamus; while

JAW OF MARSUPIAL ANIMAL.

the jaw of a marsupial animal, unknown among the existing race of beings, has been found in the Stonesfield slate quarries (fig. 120.).

1505. *Domestic quadrupeds.* No nation, perhaps, has been more solicitous to improve their originally poor breeds of domesticated quadrupeds than the British; and hence their present superiority over most of those on the Continent. Under this head we commence with the ruminating animals, as the ox, the sheep, and the goat, so essential in supplying food and clothing to man; while the horse, the ass, and the dog assist him in his labour, or protect his property.

1506. *The principal breeds of oxen* more peculiar to Great Britain have been arranged by Major Hamilton Smith under nine divisions. Of these, three belong to England, three to Scotland, two to Wales, and one to Guernsey.

1507. *The long-horned or Lancaster breed* (fig. 121.), as the name implies, is remarkable for long horns; they have firm thick hides, long close hair, large hoofs, and give in proportion less milk, but more cream. They are of various colours, but are in general finched, that is, with a white streak above the spine, and a white spot inside the houghs. The improved Leicester is a slight variety, originally bred near Coventry.

THE LONG-HORNED OX.

1508. *The short-horned breed* includes those that are named the Holderness, Teeswater, Yorkshire, Durham, and Northumberland. This has been the most improved, producing usually twenty-four quarts of milk per day, and three firkins of butter per season. Their colour varies, but is generally red and white mixed; called by the graziers flecked.

1509. *The middle-horned* includes the Devon, Hereford, and Sussex breeds: they are active, hardy, and much esteemed for draught; but although they fatten early, do not milk so well as the last. The pure Devons are of a high red colour, without spots, a light dun ring round the eye, fine in bone, clear neck, thin faced, and the tail set on high: the north Devon is most esteemed for eating. The Sussex and Hereford are larger, the ox weighing from 60 to 100 stone.

1510. *The Scottish breeds* may be arranged under the Polled, the Highland, and the Fifeshire.

1511. *The Polled Galloway* is the most esteemed: it is straight in the back, the hair soft, the colour black or dark brindled, and the size not large. They travel well, and reach the London markets without deterior-

ation. The Suffolk Dun is a variety of this race. The Highland race includes several varieties, the most valuable being the West Highland, Argyle, or Skye, and the Kyloe from the Hebrides. The Norlands is another variety, with coarse hides, long legs, and of a narrow make. The Orkney or Zetland are very diminutive: an ox weighing about 60 lbs. a quarter, and a cow 40 lbs. Their colours are various, and their shapes bad; but they give an abundance of excellent milk, and fatten rapidly. The Fifehire appears an improved breed of the Highlands, crossed with the Cambridgeshire; they are black, spotted with grey; the horns small, white, and very erect: a variety occurs in Aberdeenshire.

1512. *The Welsh have two breeds*: the first is large, dark brown, with some white; the legs long and slender; the horns white, and turned upwards: these, next to the Devon, are the best in yoke, and are a cross of the long-horned; the second is lower, well formed, black with little white, and are good milkers. The Alderney or Guernsey race is proverbially small: their colour is mostly yellow or light red; marked with white about the face and limbs, and with crumpled horns. The true breed is known by being yellow within the ears, and at the root of the tail and its tuft.

1513. *Respecting draught Oxen*, we cannot refrain from here inserting an excellent and judicious remark of Pennant. "It is now," observes this sensible writer, "generally allowed, that in many cases, oxen are more profitable in the draught than horses: their food, harness, and shoes being cheaper; and should they be lamed or grow old, an old working beast will be as good meat, and fatten as well, as a young one." (*Brit. Zool.* i. 28.)

1514. *The Sheep* is scarcely inferior in utility to the ox: and the breeds now cultivated in Britain, taking all their qualities into consideration, are perhaps the most valuable in the world. It is a curious but little known fact, corroborated by history, that the famed Merino sheep of Spain originated from the English breed, sent to that country by Edward IV. as a present to King John of Arragon. (*Bak. Chron.* p. 206.) Major H. Smith estimates the present annual value of wool (1826) shorn in England, and no longer exported, at five millions sterling; which, together with about 600,000*l.* of Spanish wool and some Saxon imported, is worth about twenty millions sterling per annum.

1515. *The British Sheep*, according to Mr. Culley, may be arranged under fourteen different breeds, and some others might also be enumerated. These may be classed under two principal divisions; those derived from the ancient race being furnished with horns, while the others in general have none.

1516. *Of the horned breeds*, the most ancient is the black-faced (*fig. 122.*), still met with in some heathy parts of Yorkshire, and the adjacent northern counties: the wool is coarse and shaggy. The Norfolk and Suffolk sheep, also, have the horns large and spiral, with the face black, but the wool is short and fine: they have a voracious appetite, and a restless disposition. In the Dorset the face is no longer black, but both sexes are usually horned. This breed is remarkable for producing lambs at almost every season, and is therefore highly valuable for supplying the London markets with house lamb. The Wiltshire is a much larger variety, having no wool on the belly. The Hertfordshire is a fine productive variety, with short tails. The Exmoor comes from Devonshire: it is small, the wool long, and the face and legs white. Scotland furnishes three breeds of horned sheep; the Dun-faced, the Zetland, and the Hebridean.

THE BLACK-FACED SHEEP.

new Leicester, is distinguished by a clean head, and the excellency of its flesh. The Devonshire Nots, like the three preceding, are long-woolled; they have white faces and legs, thick necks, short legs, and large bones. The short-woolled hornless breeds are the following:—The Hereford (*fig. 123.*) have very fine wool, which grows close to their eyes, the legs and face being white: the store sheep of this county are called Collings or Rylands. The South Down, principally cultivated on the chalky downs of Sussex, have the face and legs grey, and are highly esteemed for the table. The Cheviot have the head bare and clean, and are sometimes spotted with grey or dun; the fleece is very short and fine. The Hardwicke is peculiar to the rocky districts of Cumberland, and is speckled on the face and legs.

THE HEREFORD SHEEP.

little utility in a country abounding in sheep and oxen. But to the Welsh mountaineers it is a valuable animal: the suet will make excellent candles; the meat is little inferior to venison, and those who, like us, have habitually feasted upon mountain kid, know how superior its flavour is to lamb.

1519. *The Horses of Britain*, improved as they have been by the most sedulous care, next to the Arabian are the finest in the world. Our breeds originally but ill adapted for the saddle, have progressively improved; and the crossing of our indigenous kind with those of other countries has produced four principal classes of horses,—the Racer, the Hunter, the Roadster, and the Dray Horse; to these may be added the Poney, one of our original breeds: but the best informed zoologists agree in thinking it is now impossible to trace the native regions of the original wild stock from which all these have descended. Horses were so numerous among us in the reign of King Stephen, that London, as Fitz-Stephen relates, could furnish 20,000 cavalry; but in Queen Elizabeth's reign they seem to have greatly diminished, as the whole kingdom could not supply 2000 horses for that purpose.

1520. *The Ass* is little used, and still less esteemed, in Britain; but in Spain, Italy, and other mountainous parts of Europe, its qualities are highly valued, and much care is taken to preserve the best breeds. The Dog we have already mentioned.

1521. *The Ornithology of Great Britain*, after the general observations already made on that of Europe, will be here but briefly dwelt upon. Our native birds may be arranged under three natural divisions: — 1. the rapacious; 2. the perching; and 3. the walking, running, and swimming orders.

1522. *The rapacious birds*, as in all other countries, are the smallest in number, but the most formidable in strength. Among these the Golden Eagle (*Aquila chrysaetos*, fig. 124.)

stands foremost, as being the largest known in our islands: this noble bird weighs twelve pounds, and is still found among the highest of our Welsh and Cumberland mountains; it is said also to breed in Orkney. The Erne or Sea Eagle is somewhat smaller, and is principally confined to the maritime rocks of Wales and North Britain. The Falcon tribe is more numerous in species; but the destruction to which they are doomed by game preservers has long been diminishing their

numbers: some species are almost extirpated, and nearly all are now become rare. The Osprey (*Pandion Haliaetus*), or Fishing Eagle, is now seldom met with. Our two species of Henharrie (*Circus cyaneus* and *cinerascens*) were first discriminated by that excellent ornithologist Colonel Montagu. The Owls are similar to those of the Continent, but the great Snowy Owl has only of late years been detected in the north of Scotland as a native bird. The Eagle or great horned Owl is of the same size; the former hunting by day, the latter by night. The Barn or White Owl is known to every farmer, and appears to be distributed over the whole habitable globe.

1523. *The toothed-bill or perching birds* (*Dentirostres* Sw.) are those furnished with a notch to their bill, by which their food is held firm before it is swallowed. Some are formed to climb, others to hop on the ground, and a few catch their food (like the swallows) upon the wing. They are united to the rapacious order by the shrikes or butcher-birds, so called from their singular custom of impaling insects and small birds upon the thorns round their nests. Three species of these birds are known in Britain. The melody of the Blackbird and Song-thrush need not be eulogised; and during spring and summer our woods and hedges are enlivened by numbers of warblers, or small insectivorous birds, which visit us in the breeding season: among which the Nightingale is most conspicuous. Large flocks of Finches, and similar hard-billed birds, feast, in winter, upon the red berries of the black and white thorn; while Crows, Starlings, and Fieldfares devour prodigious quantities of slugs, worms, and other animals noxious to the farmer. The Woodpeckers, Creepers, and Titmice prey only upon those insects prejudicial to trees; while the Swallows, during summer, join with the warblers in keeping within due bounds the myriads of insects, which would otherwise increase to an alarming extent.

1524. *The entire-billed birds* (*Curtipedes* Sw.) are those which have no notch at the end of their bill, and never seek their food among trees: they are united to the former by the Pigeons, and comprise the gallinaceous, wading, and swimming tribes. Among the first we possess the Partridge, Grouse, and Quail, but more particularly the Great Bustard, the largest of the European gallinacea: from its size, and the delicacy of its flesh, this noble bird has been much persecuted by sportsmen, and is gradually disappearing from its ancient haunts: it is now, we believe, only preserved on some estates in Norfolk: its weight is about 25 lbs., and its flesh excellent. To enumerate the wading and swimming birds would far exceed our limits: they visit us principally in winter, and depart in spring. If the cold is very severe, immense numbers come to our shores from the polar regions, and afford an additional supply to the London markets.

1525. *The exterminated birds* are very few; for although some, as the Egret (fig. 125.) and the Crane, are no longer common in Britain, yet individuals are sometimes met with, showing that man and not nature has scared them from their hereditary range. To class such birds as not belonging to the British fauna implies a misconception of the fundamental principles of geographic zoology. Perhaps the only extirpated species is the cock of the wood, or capercaillie grouse (*Tetrao Urogallus* L.), a noble bird of game, weighing near thirteen pounds; once common in the fir forests of Scotland, but which has not been seen, it is said, since 1760.

1526. *Our domesticated birds* are well known. The Pheasant originally came from Asia Minor; the Guinea Hen from Africa; the Peacock and Fowl from India; and the Turkey from America.

1527. *The fishes*, both marine and freshwater, are numerous: most are edible, and many highly esteemed. The Whale and other cetacea, as before remarked, are mostly confined to the northern shores: but those of the west are famous for the herring and pilchard fisheries. The John Doree is as remarkable for its

grotesque form as for its exquisite flavour. The Turbot, Cod, Sole, &c. are well known. Our chief river fish are the Salmon, Trout, and Char; and these are principally furnished by the northern counties. The salmon fisheries are highly important, and have long engaged the attention of the legislature: the eggs of one fish will often exceed 15,000. The Char is confined to the lakes of Cumberland and Westmoreland; those of Windermere are the best, and when *potted* become a great delicacy. The Herring and Sprat supply the poor, during winter, with a wholesome dish; while the citizens of London consider

126

WARTY EFT.

another species, called the White Bait, as possessing a peculiarly fine flavour. The Anchovy is not unknown in some of our estuaries; and even the Flying-fish has occasionally wandered to the Welsh coast.

1528. *The reptiles of Britain*, known in a living state, are very few. The Hawks-bill Turtle is a rare visitant. Besides the Warty Eft (*Lacerta palustris* Lin., fig. 126.), we have two other water

lizards, and probably as many species inhabiting the land. Of the Frog and Toad two sorts of each occur. The snakes and the blind-worm are

127

COMMON VIPER.

harmless; the Common Viper (fig. 127.) being the only venomous reptile: yet this species varies so much in its colours, that naturalists have described it under several names. The Great or Gigantic Frog of Pennant is no other than a variety of the common toad. Dr. Leach ascertained this fact by examining 600 specimens, collected by himself and a friend, near Loch Ranza.

1529. *Extinct reptiles.* The researches of geologists have brought to light the remains of such gigantic and extraordinary reptiles that, but for such indubitable proofs, their existence might be thought fabulous. At the head of these we may place the *Megalosaurus*, resembling both a lizard and a crocodile, whose probable length was near 40 feet! The *Ichthyosaurus*, uniting the characters of a lizard with the snout of a dolphin, the teeth of a crocodile, the fins of a turtle, and the vertebræ of a fish, is scarcely less wonderful. The *Plesiosaurus* is still more extraordinary; for with the fins of a turtle, it had the head of a lizard, and a long neck, formed like the body of a serpent. Lastly, the remains of several distinct species of crocodiles have been discovered in similar strata. All these attest the existence, at some unknown period, of a stupendous race of aquatic monsters, which have long been swept away from the existing animal creation.

1530. *The other marine animals* of our seas are more numerous than might be expected in latitudes so far north. And although their strange and often grotesque forms awaken not the attention of the illiterate fisherman, the observer of nature will be struck by the singularity of their construction, and the brilliancy of their colouring. Among the radi-

128

BLACK LINE WORM.

ated animals, vast shoals of transparent *Medusæ* wander about the coast during summer, and are frequently by a sudden change of wind cast up on the beach in great numbers. But the deep recesses of the ocean frequently give to the nets of the fisherman animals still more singular. The Black Line Worm, or Sea Long Worm (*Linnæus longissimus* Sow., fig. 128.), whose mouth is hardly a quarter of an inch wide, is said, by the fishermen of Newhaven, frequently to measure twelve fathoms in length: it is soft, and so fragile, that the entire animal seems not yet to have been procured.

Mr. Symmonds, by whom it was first particularly described, measured a detached piece, which was twelve feet long. The warm shores of the Cornish and Devonshire coast furnished the celebrated Montagu with constant employment, in the investigation of those new or little known marine animals, which daily rewarded his assiduous research.

129

MAY-BLOSSOM CORAL.

1531. *Nor are our corals and corallines* devoid of interest or beauty. With the invaluable work of Ellis upon these animals, and a common microscope, what an excitement is held out to the frequenters of watering-places, for exercise in collecting, and curiosity in examining, these wonderful little creatures! They would exhibit congregations, or societies, united together, as if conspiring to form their habitations into the beautiful representations of leaves or mosses. Our celebrated countryman Ellis was the first to make known the true nature of those plant-like productions generally termed corallines. Of Corals, we have few native species; the largest and most elegant is the May-blossom coral (*Caryophyllia ramea*), (fig. 129.), common in the Mediterranean, and occasionally

found upon the Cornish coast: it is cinnamon-coloured; and retains, for many years, a slight scent, like that of hawthorn.

1532. *The conchology of Britain*, in the number and interest of its species, compensates for its deficiency in large or richly coloured objects. The beautiful varieties of *Pecten opercularis* are, nevertheless, an exception; for they are frequently variegated with the most lovely tints of yellow, orange, pink, and deep red, that the painter can produce: this shell, common in the west of England, also affords a nutritious food to the lower classes. The most celebrated of our edible shell-fish is the oyster, well known and highly prized by the luxurious Romans; and every one is acquainted with the superior excellency of those from Colchester and Milton. Fluvatile shells, in a country so humid and watered as Britain, are more abundant than towards the south of Europe. Most of our rivers produce *Unio pictorum* (fig. 130. *a*), and *Unio ovatus* (*b*): *Cyclas cornea* (*d*) is generally found in the same situations. Our ponds and stagnant waters are frequently covered with *Lymneus palustris* (*e*), *ovatus* (*g*), and *Planorbis corneus* (*l*); while the large Duck-mussel (*Anodon anatinus*) (*c*) burrows in the muddy bottom. A little fragile shell, *Succinea amphibia* (*f*), crawls upon rushes and aquatic plants; and *Physa fontinalis* (*h*), *Ancylus lacustris* (*i*), and *Planorbis vortex* (*k*) prefer clear shady streams and ditches overhung with wood.

1533. *Our native pearls*, although but little known, even by name, in modern days, were reckoned by the Romans among those productions for which Britain was celebrated. They are the produce of a fluvatile bivalve shell, the *Unio margaritifera*, (fig. 131.), still common in many of our northern counties. But it was on the banks

of the Welsh rivers that this British pearl fishery of our ancestors was chiefly carried on; and pearls of a small size might no doubt be still procured in such places as afford an abundance of the shell.

1534. *Insects.* Considering the nature of our climate, so unfavourable to the rapid propagation of these beings, it may excite surprise, that more than 10,000 different species have actually been found to inhabit Britain, and possibly some hundreds still remain undiscovered. Yet the bee may be reckoned the only insect whose services are immediately and obviously beneficial to man. Among the butterflies, we have many of great beauty; while *Eurymus Europome*, or the Clouded Sulphur (fig. 132.), is considered one of the rarest British insects. From the statements which have been published, it seems not unreasonable to hope, that the efforts now making in Devonshire and Ireland for introducing the silk-worm may eventually be successful.

1535. *Scotland.* The zoology of Scotland exhibits many of the arctic animals as common inhabitants, which are only known as rare visitants, to the western shores of England; in other respects it does not materially differ from that of South Britain. The northern islands are peculiarly interesting to the naturalist, as giving shelter to innumerable wild fowl, and to many peculiar land birds, as the Ptarmigan and the Golden Eagle. These seas, moreover, are occasionally visited by many of the large whales, whose usual resort is in the polar regions. The great horned or Eagle Owl, one of our rarest birds,

is found to breed in Orkney. The Highlands are famous for an abundance of Grouse, the red species (*Lagopus scoticus*, fig. 133.) being the only bird peculiar to Great Britain. The Wolf appears to have been extirpated in 1680; but the Roebuck is still found wild in Fifeshire. The shores and rivers abound with excellent fish; and large quantities of Salmon are sent to the English market.

1536. *The domestic animals*, particularly the oxen and sheep, as might be expected from the temperature of the climate, and the diminished luxuriance of pasture, are all of a small size; in other respects they are highly valuable. The polled or hornless cattle, with the Highland and the Fifeshire, have already been particularly noticed. The *Kyloe* breed are so named, because in their progress to the south from the Hebrides, they cross the kyloes or ferries in the mainland and Western Islands. (*Ham. Smith.*) The same writer considers that the sheep of this kingdom spring from three principal breeds: the first is generally named dun-faced sheep; they are a small, horned race, said to have been originally imported from Denmark or Norway, and are still found, with slight variations, in the north of Scotland and the isles. In Kincardineshire, this breed is known by its yellow face and legs, and by the dishevelled texture of its fleece, which is in part coarse, and in part

HIGHLAND PONY.

remarkably fine wool; its flesh also is delicate and highly flavoured. The Zetland breed carry a very fine wool, in three different successions yearly, two of which resemble long hair more than wool, and are called Fors and Scudda. The wool is of various colours. The Hebridian sheep is the smallest animal of its kind; its horns are usually short and straight, the face and legs white, the tail very short, and the wool of different colours. This breed, like the two preceding, from being intermixed and crossed with others, will probably be soon extinct.

1537. *The Highland Ponies* and Shetland Ponies (fig. 134.), notwithstanding their diminutive size, are greatly esteemed for their activity and strength.

1538. *Among the numerous breeds of dogs*, there appears to be three more particularly found

SCOTTISH GREYHOUND.

in Scotland: the first is the true Shepherd's Dog, or Colly, which is still preserved, unmixed, in many of the sheep districts. The second is the Zetland Hound, which approaches in character to the Greenland Dog; while the Scottish Greyhound (fig. 135.), common in the Highlands, is possessed of great sagacity, strength, and swiftness. (*Flem. Brit. An.* p. 11.)

1539. *Ireland.* The zoology seems to have shared in the general neglect with which this fine island has, until lately, been treated; nor are we prepared to show if any, and what, peculiarities belong to its natural history. Even local lists, which constitute the most valuable materials of a fauna, are altogether wanting. The Irish

Wolf Dog, called also the Irish Greyhound, has generally been thought peculiar to this island; but others consider it the same breed as the French mâtin (*Canis laniarius* L.) It is a noble animal, standing near four feet in height, and seems to have been mainly instrumental in clearing the country of the numerous wolves which once over-ran it. Its

FOSSIL ELK.

particular services being no longer in request, the breed has been neglected, and probably, will be soon extinct. The Horses seem to be of a small and unimproved breed; and where agriculture has been so little attended to, we may presume the cattle and sheep are much inferior to those of Britain. Yet Ireland exports vast quantities of salted provisions, besides the supplies furnished to our navy and shipping interest. The Fossil Elk of this country

HEART COCKLE.

(fig. 136.) has long excited the attention of naturalists; and its remains are of frequent occurrence in beds of shell marl, beneath peat. Its antlers are enormous, measuring, from the extreme tip of each, no less than ten feet ten inches, and from the tip of the right horn to its root, five feet two inches. Remains of the same animal have been also found in England, and a very perfect specimen in the Isle of Man. It deserves notice, that several well-known shells of the West Indies, with tropical seeds and nuts, are occasionally found on the Irish shores; these localities also furnish the conchologist with several native shells, seldom seen on the British coasts, particularly the *Iso-cardia cor*, or Heart Cockle (fig. 137.), not unfrequently fished up in the Bay of Dublin.

SECT. III. *Historical Geography.*

1540. *Britain*, according to the concurrent testimony of all ancient writers, *was originally peopled from Gaul*, and its earliest inhabitants belonged to the same Celtic race who occupied that country and Spain. It was one of the parts of the world last known to the Greeks and Romans. For a long time it appears to have been noticed only as a country supplying tin; a rare and useful metal, not then found in any other part of Europe, or in Western Asia. The Cassiterides, or islands of tin, of which mention is made by Herodotus, included, in Major Rennell's apprehension, a vague idea of the whole group of the British islands; though the appellation might originally be restricted to the Scilly Islands, and to the south-western promontory of England, from the Lizard Point to the Land's-end, where alone tin was to be found. To obtain this valuable mineral, the coasts of Britain were at an early period sought by the ships of various mercantile states, especially the Carthaginians; and the *tin* of Tarshish, mentioned by Ezekiel, was doubtless brought from the mines of Cornwall. Voyages were made thither by Himilco, and by Pytheas, who even penetrated to the northern extremity of Scotland; but of the observations made by these navigators, few notices are found in the works of ancient writers.

1541. *Britain was invaded by the Romans*, about fifty-five years before the Christian era. Of the thirty tribes of barbarians among whom the country was then divided, the most considerable were the Belgæ in the west, the Brigantes in the north, the Silures in South Wales, the Iceni in Norfolk and Suffolk, and the Cantii, who occupied Kent and part of Middlesex. The latter had made some progress in agriculture and the arts of civilised life; but the other inhabitants derived their subsistence from flocks and herds, clothed themselves in skins, and painted their bodies; they had another custom similar to that of the natives of Otaheite, by which a number of their chiefs held their wives in common. To these rulers a people turbulent by disposition, and warlike by habit, would be little disposed to pay uniform obedience; but their precarious authority derived effective support from the influence exercised by the Druids, in one of the most terrible forms of superstition that ever enslaved the human mind. This influence might at times be beneficially employed in appeasing the animosities that arose between one state and another, and in diffusing among them that spirit of concord which was soon to be awakened by a sense of common danger. When that crisis arrived, the Britons were by no means unprepared; besides all the ordinary implements of war, they had armed chariots, which they managed with surprising dexterity; and they were all united in a species of political confederacy, of which Cassivelaunus was the head. With all these advantages, however, they could not prevent the landing of Julius Cæsar, or keep the field against him: but that powerful conqueror encountered a fierce resistance from foes whom he had expected to overawe by the terror of his name, and was prevented by more urgent affairs from prosecuting an enterprise of which the difficulties were not likely to be compensated by its glory. Under the first emperors the Britons were held in a state of subjection rather nominal than real. It was in the otherwise inactive reign of Claudius that an expedition on a great scale was first attempted. The hardihood of Caractacus, and the heroic desperation of Boadicea, failed of exciting an effectual resistance to the disciplined legions of Rome, whose victorious progress was continued during the reign of Nero. In that of Domitian, the most timid of all the emperors, their dominion was extended by the wisdom and valour of Agricola, who defeated the Caledonians under Galgacus, at the foot of the Grampians; and the only part of the island which remained unsubdued was the region which lies north of that natural rampart.

1542. *The Britons now subjected to the Roman empire* were compelled to cultivate the habits and arts of peace: but this change, which might have been beneficial, proved injurious, when that empire, weakened, distracted, and verging to its decline was compelled to withdraw its protection from its distant provinces. The Scots and Picts, emerging from their mountain fastnesses, then broke in, and committed dreadful devastations among their unwarlike neighbours. The Romans, for the protection of their suffering vassals, had recourse to the feeble expedient of frontier walls; first, one between the Forth and Clyde, called the Wall of Antonine, and afterwards a similar rampart between the Tyne and Solway, called the Wall of Severus. These bulwarks proving inefficient against such daring invaders, the degenerate Britons made the most earnest and piteous appeals to Rome for protection. This was occasionally afforded; but the exigencies of the empire became continually more urgent; and about the middle of the fifth century, the Roman forces stationed in the island were entirely withdrawn, and the Britons were warned that they must thenceforward depend entirely on their own resources.

1543. *The Saxons were called in as allies*, about forty years after the dissolution of the Roman government. These hardy adventurers, originating from the north of Germany, and occupying the line of coast from the mouth of the Rhine to Jutland, were equally formidable as warriors and as mariners, and had long infested by their piracies the neighbouring parts of Britain and Gaul. They eagerly accepted an invitation to a country which they knew to be in all respects superior to their own. In the year 450 they sent 1600 men under their chiefs Hengist and Horsa; who having with this small force obtained

an easy victory over the Scots and Picts, determined to dispossess the Britons of a territory which they could not defend against so contemptible a foe. The successes that attended the enterprise of the two brothers attracted numerous bands of their countrymen; and in the course of a century, colonies arrived from the mouths of the Elbe, the Weser, and the Rhine, chiefly composed of three valiant tribes, the *Jutes*, the *Old Saxons*, and the *Angles*. The *Old Saxons* claimed precedence as leaders of the enterprise, and in after-times as founders of the monarchy; the *Jutes* claimed the merit of erecting in Kent the first independent kingdom; and the *Angles*, distinguished for their numbers and success, had the honour of bestowing a permanent name on the country. After a long and sanguinary struggle of one hundred and fifty years, they compelled the Britons to retire into Wales and Cornwall, and so absolute was the change, that not a trace of the Celtic name and language has been left in the fairest portion of the island.

1544. *Thus was established the Heptarchy, or Seven Saxon kingdoms, in Britain: viz.* 1. Kent; 2. Sussex, including Surrey; 3. East Englas, including Norfolk, Suffolk, the Isle of Ely, and Cambridgeshire; 4. Wessex, including all the southern counties from Berkshire to Cornwall; 5. Northumberland, including all the northern counties of England, and the southern counties of Scotland to the Frith of Forth; 6. Essex, including Essex, Middlesex, and part of Hertfordshire; 7. Mercryc, or Mercia, the largest division, including the midland districts of England to the confines of Wales.

1545. *About the year 800 these small states were united into one kingdom, under the name of England, by Egbert king of Wessex, a descendant of the first Saxon invaders.* On assuming the sovereignty, he endeavoured to introduce the improvements which he had learned to appreciate during his residence at the court of Charlemagne. The Anglo-Saxon dynasty derived its chief lustre from Alfred, justly revered as the founder of the English constitution, and one of the wisest and most virtuous monarchs that have appeared in any age or country. The judicious division of the kingdom into shires, hundreds, tithings, and decenaries; the establishment of a general system of mutual responsibility among his subjects, by which life and property were rendered secure, without any restraint on liberty; the institution of courts for the administration of justice; and the formation of a code for their guidance, embodying the laws derived by the Saxons from their German progenitors, and still recognised as the basis of the *common law* of England; — these and other measures of polity might have required, and would have illustrated, a reign of uninterrupted tranquillity. But Alfred shone as a warrior no less than as a legislator: he delivered his country from the cruel and overwhelming thralldom of the Danes; and in creating a navy to encounter those pirates on their own element, he may be said to have laid the foundation of the maritime supremacy of Great Britain. In the course of the ensuing century, however, the Danes regained the ascendancy; and in 1017, Canute king of Denmark and Norway, the most powerful monarch of his time, added England to his dominions. It was held successively by two of his sons, Harold and Hardicanute; but on the death of the latter, it was restored to the Saxon dynasty, and Edward, called the Confessor, ascended the throne.

1546. *The conquest by William of Normandy, in 1066, overthrew for a time the liberties of the people of England.* Claiming the crown by virtue of a pretended grant from Edward the Confessor, and acquiring it by victory over Harold II., himself an usurper, to the prejudice of Edgar Atheling the rightful heir, he maintained by tyranny a dominion gained by fraud and violence. He punished all persons who had taken up arms against him by the forfeiture of their estates, which he conferred on his Norman vassals; and he compelled all those who were not found in arms against him to take out patents to hold their lands of himself. Having ordered a general survey of all the lands in the kingdom, he changed the nature of the tenure from *allodial* to *feudal*, to be holden of him by knight's service; thus enthralling the people by a military despotism. He endeavoured to supplant the English language by that of the Normans, which was employed at court, in council, and in all public proceedings; and it was a fixed maxim of his reign, that no native of the island should ever be advanced to any dignity, civil, religious, or military. The natural antipathy of the English to their oppressors was strengthened by this partiality, and many ages elapsed ere the two nations were thoroughly incorporated. One of the consequences of the acquisition of the English crown by William was to convey to the kings his successors certain claims on the French territory, which led to long, expensive, and sanguinary wars. The second of those successors, his son Henry the First, by his marriage with Matilda, daughter of Malcolm king of Scotland, and niece of Edgar Atheling, conciliated a people zealous for the rights of their native princes, and anxious for their re-establishment.

1547. *The Saxon line was restored in the person of Henry the Second, surnamed Plantagenet, son of Geoffry of Anjou, who married Matilda, daughter of Henry I.* This prince, in the right of his father, was master of Anjou and Touraine; in that of his mother, of Normandy and Maine; in that of his wife, of Guienne, Poitou, Xaintonge, Auvergne, Perigord, Angoumois, and the Limousin. To these states he afterwards annexed that of Bretagne. The possession of provinces composing above one third of the French monarchy, and superior in opulence to the rest of the territory, rendered this vassal more powerful than his

liege lord, and contributed, with other causes, to provoke that rivalry which for ages existed between England and France. The princes of the house of Plantagenet exhibited an energy of spirit, some in good, and others in evil, which strongly affected the character and interests of the nation. The valour or the policy of Henry the Second acquired for him the sovereignty of Ireland; the prowess of his son Richard, however misdirected, kindled and kept alive the military spirit of the people; the proud determination and inflexible constancy of Edward the First annexed to Wales to his dominions, and for a time subjugated Scotland; while his wisdom as a legislator gained for him the appellation of the English Justinian. The victories of Edward the Third in France shone among the most splendid achievements of a chivalrous age; and the entire conquest of that kingdom by Henry the Fifth might have led to important changes, had it not been prevented by the premature death of that accomplished prince. The consequent loss of the French provinces was a reverse of which the remembrance was soon effaced by the contending claims of the houses of York and Lancaster for the crown of England, which, after a civil war of nearly sixty years, were adjusted by the marriage of Henry the Seventh with Elizabeth, daughter of Edward the Fourth. Among the memorable events that occurred under the Plantagenets, may be noticed the signature of Magna Charta, extorted by the barons from King John; the rise of the House of Commons in the reign of Henry the Third, and the reformation of the church, commenced by John Wickliffe in 1369.

1548. *The reign of Henry the Seventh was signalised by the overthrow of the feudal sway, and by the introduction of the modern system of polity.* Other innovations, deeply affecting the character of the English people, ensued under the successive sovereigns of the line of Tudor, until the death of Elizabeth. The period was in all respects one of the most interesting in the history of England, of Europe, and of the world. The invention of printing, the navigation to India, the discovery of America, the reformation in Germany, the balance of power among European states, the changes in the mode of warfare caused by the introduction of fire-arms, co-operated to produce a progressive and permanent change in the social and political condition of mankind. England participated most largely in all the advantages resulting from the new order of things; and though the emancipation of the kingdom from papal tyranny was effected by the sovereign in rather an irregular manner, without much deference to the inclinations of the people, it accorded too well with their independent spirit not to gain their hearty support and concurrence. In the reign of Elizabeth, various causes contributed to accelerate the revolution of public opinion; and after the destruction of the Spanish armada, which the Roman pontiff had presumed to call *invincible*, the thunders of the Vatican lost all their terrors. The most strenuous exertions were made to strengthen the maritime power of England, as well as to employ it in liberating other states from the oppressions under which they had long groaned, and in extending her commercial intercourse with them. The result of these measures was to raise the nation to a very prosperous and flourishing condition, and to overturn the lawless domination of the nobles, substituting for it, however, an authority almost absolute on the part of the sovereign.

1549. *The union of the two crowns on the accession of James the Sixth of Scotland to the throne of England, terminated those dissensions and animosities, which had proved alike injurious to both countries.* The reign of James was peaceful; but that of his successor was marked by troubles which a sort of fatality seems to have allotted to the house of Stuart. The impolitic and despotic conduct of Charles the First, coming into collision with the rising spirit of freedom, led to a struggle in which he lost both his crown and his life. In the interregnum which ensued under the Commonwealth, the vigilant, energetic, and decisive policy of Oliver Cromwell exercised a commanding influence over every cabinet in Europe. Restored by the predilections of the people for a monarchical government, Charles the Second suffered England to lose the ascendancy which she had attained; but the apathy of this luxurious, unprincipled, and venal prince was at least favourable to the growth of popular influence, and to the establishment of important securities for the liberty of the subject. The infatuated conduct of James the Second, under the insidious direction of priests and jesuits, led to the revolution of 1688, from which glorious epoch may be dated that happy equilibrium of the different powers, and that admirable system of public right, which have rendered the British constitution the envy and admiration of the civilised world.

1550. *From the revolution of 1688 to the present time, Great Britain has had frequent occasions to rejoice in the stability of her constitution amidst the convulsions which have agitated all Europe.* During this period, her industry, commerce, and wealth rapidly rose to a height unparalleled in any other nation ancient or modern; but her political power sustained various fluctuations. She acquired in the East and in the West two empires, each far more extensive than her own territory, and the one far more populous. That in the East she retains, and is continually extending; that in the West, having become independent by the aid of France and Spain, is her rival in commerce, and manifests a disposition to dispute, at no distant period, her maritime supremacy. Among the memorable transactions and events of this period may be ranked the union with Scotland in 1707; that with Ireland

in 1801, the Scottish rebellions in 1715 and 1745; the Irish rebellion in 1798; and a series of wars with France, occurring at intervals rarely exceeding eight or ten years. Of these wars the issue has generally been glorious; the last contest, arising from the revolution of France, was distinguished by the most brilliant naval achievements, and afterwards by successes which raised the military glory of England to a level with her maritime renown, rendering her power and influence paramount among the states of Europe.

SECT. IV. *Political Geography.*

1551. *The constitution of Great Britain* centres in the laws by which the country is governed, and in the union of powers by which the laws are made and the government is administered. The *legislative* power is vested in the Parliament, consisting of the KING, an hereditary sovereign; the LORDS, an hereditary aristocracy; and the HOUSE OF COMMONS, consisting of members chosen by the people from among themselves, and therefore said to represent the commons of the realm. The *executive* power is entrusted to the king.

1552. *Of the three estates of the realm thus composing the legislature, the King is the highest:* he is the head or chief of the parliament; and except in extreme cases, a parliament cannot be held unless convoked by him, nor can it except by him be dissolved or prorogued. His *assent* is requisite to give the force of law to any measure proposed by either of the two houses, and agreed upon by them; and he has the indubitable right, although it has not been exercised for more than an hundred years, of withholding the *royal assent* from any proposed enactment. These are, in general, the limits of his legislative functions. Propositions of laws, or *bills* as they are technically called, may be brought forward in either house; all money bills *must* take their origin in the House of Commons; but only in one instance can the king initiate an act of parliament, and that is, an act of grace, for the pardon of persons after a rebellion, or for the release of insolvent debtors. Such an act properly emanates from the throne as the fountain of mercy. It is introduced, with the royal assent under the sign-manual, in the House of Peers, where it is immediately read a first, a second, and a third time, and sent to the House of Commons, where it is passed through all its stages with the same promptitude.

1553. *The King is not supposed to hold his throne by divine right*, or in virtue of any indefeasible hereditary claim. The nation, by its supreme council, has dictated certain rules of exclusion with regard to the succession, of which the most important is, that the sovereign shall maintain the protestant reformed religion, and, either at his coronation or on the first day of the first parliament, shall repeat and subscribe the declaration against popery. Marriage of the sovereign with a subject is held to be null, and the issue incapable of succeeding. But the crown is with these limitations hereditary, and on the death or demise of the king, his heir becomes instantly invested with the kingly office and regal power. Even at the Revolution, when a decided change of dynasty took place, a convenient fiction was employed; the flight of the king was construed into a voluntary abdication, the throne was pronounced to be vacant, and William and Mary, prince and princess of Orange, were declared to be king and queen.

1554. *The royal prerogative is in most particulars as ancient as the law itself;* and it is a great error to infer from the terms legislative and executive, that the king is a mere magistrate or officer-empowered to *execute* the ordinances of parliament. He is "the universal occupant;" and, by a constitutional fiction accordant with the feudal policy, all lands are held mediately or immediately from the crown. Thus he is entitled to all lands left by the subsiding of the sea; and estates may revert to him by escheat from the commission of crime by their possessors. He is sovereign in all seas and great rivers; he alone has a prerogative to erect beacons and lighthouses; he is entitled to all royal mines of gold and silver, and is entrusted with the coinage. All persons born in any part of his dominions and within his protection are his subjects, and owe to him an allegiance which they can neither renounce nor transfer to any foreign prince. He is supreme head of the church within his dominions; and as patron paramount of all the benefices in England, he has a right to present to all dignities and benefices of the advowson of archbishoprics and bishoprics during the vacancy of their respective sees. He is the fountain of justice, and has an undoubted prerogative in creating officers of state, ministers, judges, and other functionaries. To him, as *parens patriæ*, belongs the care of all who are unable to take care of themselves; he has an original right to superintend the disposal of charities; and in all such cases the application is to the Court of Chancery. He has, in certain cases, the high prerogative of pardoning, and likewise that of issuing special proclamations for the prevention of offences. The power of making war or peace is lodged singly in the king. In virtue of his prerogative, the administration and rules of law differ between him and a private person; he is held to be incapable of doing wrong, and if an unlawful act be done, the minister instrumental in that act is alone obnoxious to punishment. By virtue of his prerogative the king may make grants and letters patent, conferring various rights and privileges. Lastly, the king cannot be attainted, and is never a minor; though when the crown has devolved to a very young heir, it has been thought prudent to appoint a regent, or council of regency. The same

expedient has been adopted when, by reason of grievous illness, the exercise of the royal functions has been interrupted.

1555. *The revenues of the crown* are, in a legal sense, very extensive; for all supplies granted by parliament are given to the king. But of these much the largest proportion belongs to the public or its creditors; that which pertains to the king in his distinct capacity, and which is called the *Civil List*, amounts to but a moderate provision (out of a revenue of fifty or sixty millions) for the support of the honour and dignity of the crown. In 1813-14, when a detailed report was made on the subject, the entire allowance, which in the beginning of the reign was 800,000*l.*, had been raised to 1,000,000*l.* Besides this, the debts of the civil list had been paid at different periods during the fifty-four years of the reign of George III., to the amount of 3,113,000*l.* His majesty during that period had also drawn 172,000*l.* from the $4\frac{1}{2}$ per cent. West India, and sums from the droits of the admiralty, augmenting it to 1,653,000*l.*; raising the whole to 4,866,000*l.*, and forming an annual addition of about 90,000*l.* The civil list comprised not only the provision for the personal expenses of the royal family, but that which was allotted for various branches of the public service. From it were paid the salaries of the judges, amounting to 33,000*l.*; those of ministers at foreign courts, 90,000*l.*, with equipage, presents, &c.; extraordinary disbursements, 153,000*l.*; pensions, 151,000*l.*; small salaries and offices of the treasury department, 60,000*l.*; secret service money, 100,000*l.* All these deductions being made, the sum remaining applicable to the private expenditure of the royal family was little more than half a million. Of this only 60,000*l.*, the allowance for the privy purse, was at the immediate disposal of his majesty. The rest, including all the branches of state and expenditure, was paid by the steward, the chamberlain, the master of the horse, and other officers specially appointed for the purpose, and accountable to parliament.

1556. *On the commencement of the reign of William IV.*, the civil list was entirely new-modelled. It was now limited to the personal expenses of the sovereign, and the maintenance of his state; while the branches of administration hitherto defrayed out of it were charged upon the Consolidated Fund. The sum of 510,000*l.* was granted, under the following heads:—

Privy purse, King's,	-	-	£60,000	Salaries in the department of	
Queen's	-	-	50,000	Royal bounty	- £9,500
Maintenance of royal establish-				Churches	- 3,200
ment	-	-	171,000	Poor of London	- 1,000
Salaries in the department of				Home secret service	10,000
Chamberlain	-	-	64,450	Pensions	- 75,000
Steward	-	-	36,500		
Master of the horse			28,500		
Master of the robes			850		
					£510,000

1557. *Thus the royal prerogative, which would otherwise preponderate, is counterbalanced by the control which the representatives of the people in parliament exercise over the public purse.* The king, without a grant from his people, has scarcely any revenue. He has the prerogative of commanding armies and equipping fleets; but without the concurrence of his parliament he cannot maintain them. He can confer appointments to offices; but without his parliament he cannot pay the salaries. He can declare war; but without the aid of parliament he cannot carry it on. He has the exclusive right of assembling parliaments; but by law he must assemble a parliament every three years, if necessity obliged him not to convoke it much oftener. Though head of the church, he cannot alter the established religion, or call individuals to account for their religious opinions. He cannot create any new office inconsistent with the constitution or prejudicial to the subject. He has the privilege of coining money; but he cannot alter the standard. He has the power of pardoning offenders; but he cannot exempt them from making compensation to the injured parties. Even with the military power he is not absolute, since it is declared in the Bill of Rights that a standing army without the consent of parliament is illegal. The king himself cannot be arraigned; but if any abuse of power be committed, those who were either the advisers or the instruments of the measure may be impeached and tried before the House of Lords; in which case it is of no avail to plead the king's command, or to produce his pardon. A dissolution of parliament does not abate an impeachment, neither can the royal authority interpose to stay or suspend its course. Other restraints on the prerogative exist in the uncontrolled freedom of speech in parliament, secured by the Bill of Rights, and in the important provisions by which, during the reign of George III., the independence of the judges was established.

1558. *The House of Lords* is composed of the lords spiritual and temporal of England; sixteen temporal peers of Scotland; one archbishop, three bishops, and twenty-eight temporal peers of Ireland. The roll of the lords spiritual and temporal forming the House of Peers, in the session of 1833, exhibits 426 lords, including the catholic peers of England. They are thus distinguished:—

Royal dukes	-	-	-	4	Bishops	-	-	-	27
Archbishops	-	-	-	3	Barons	-	-	-	181
Dukes with English titles	-	-	-	21	Peers of Scotland	-	-	-	16
Marquesses	-	-	-	19	of Ireland	-	-	-	28
Earls	-	-	-	109					
Viscounts	-	-	-	18	Total	-	-	-	426

1559. *The Lords Spiritual* are, for England, two archbishops and twenty-four bishops; and for Ireland, one archbishop and three bishops; the English hold their seats for life, the Irish by rotation. The archbishops rank above all dukes except the princes of the blood; the bishops next below viscounts.

1560. *The Lords Temporal* are not limited in number, it being the prerogative of the king to raise to the peerage any of his subjects whom he thinks deserving. The creation is either by writ or patent, the former mode being the most ancient, and the latter the most secure and honourable. The temporal peers consist of dukes, marquesses, earls, viscounts, and barons. The title of *duke* did not exist in England until the reign of Edward the Third; that of *marquess* was introduced in the reign of Richard the Second; that of *earl* is of very ancient origin, corresponding in dignity with the French title of *count*. Viscounts were created in the time of Henry the Sixth. In former times the title of *baron* was general among the nobility, and every peer of superior rank held also a barony; but in the course of a few generations the two titles might be divided, the one continuing to the male descendants, the other passing to the heirs-general: in later times, earls and viscounts have been created without annexing a barony to their higher honours; wherefore all peers are not barons. Although the right of adding indefinitely to the number of peers forms part of the royal prerogative, it has been very sparingly and cautiously exercised.

1561. *The sixteen Peers of Scotland* are, by the articles of union, elected by the peers of that country from among themselves; and in case of a vacancy by death or legal incapacity, recourse is had to election for supplying the place vacated. The election of the sixteen peers is renewed for every parliament.

1562. *With respect to the Peers of Ireland*, it was established by the act of union that four lords spiritual by rotation of sessions, and twenty-eight lords temporal elected for life by the peers of Ireland, shall be the number to sit and vote on the part of Ireland in the House of Lords of the parliament of the United Kingdom.

1563. *As a supreme court of judicature*, the House of Lords exercises jurisdiction in civil causes upon appeals or writs of error from the inferior courts; and in criminal questions, when brought before them, by presentment of the House of Commons, in the form of an impeachment.

1564. *All members of parliament have the privilege for themselves and their menial servants of being freed from arrests or imprisonment for debt or trespass*; but not from arrests for treason, felony, or breach of the peace. The peers have other privileges peculiar to themselves. In all cases of treason, felony, or misprision, of felony, a nobleman is tried by his peers; but in misdemeanours, as libels, riots, perjury, and conspiracy, he is tried like a commoner by a jury. In judicial proceedings, a peer gives his verdict not upon oath, but upon his honour; he answers also to bills in chancery upon his honour, and not upon his oath; but when examined as a witness in the inferior courts or in the high court of parliament, either in civil or criminal cases, he must be sworn. Slander against a peer subjects the offender to very heavy punishment, being branded by the law with the term *scandalum magnatum*. Every Peer, by licence from the king, may make a proxy to vote for him in his absence, a privilege which cannot be held by a member of the lower house. He has also a right, by leave of the house, when a vote passes contrary to his opinion, to enter his dissent, with the reasons for it, on the journals of the house: this is usually called his *protest*. The privilege of franking letters is enjoyed by members of both houses, with restrictions as to number and weight, and by certain officers of state and other functionaries to an unlimited extent. As private individuals, the peers enjoy none of those injurious and oppressive rights which in other countries are possessed by the aristocracy, and which press so heavily on the people in general. They have no means of turning aside the course of justice, or of sheltering themselves from its decisions; and they defray their share of the public burdens in common with the humblest individuals. In respect to their legislative capacity, it is however to be observed, that all bills which may in their consequences in any way affect the rights of the peerage, are, by the custom of parliament, to originate in the House of Peers, and to suffer no changes or amendments in the lower house.

1565. *The House of Commons*, as a distinct branch of the legislature, is the peculiar boast of the British constitution. Through this representative assembly, while all the other great kingdoms of Europe were subject to the arbitrary rule of a monarch, or to the vexatious domination of an oligarchy, the people acquired their due share in the national councils, and established, among other rights, that of regulating the collection and distribution of the public money; causing it to be recognised as a principle, that they shall not be taxed but by their own consent. The period when the commons of England began to take a share in legislation is too remote to be exactly ascertained. In the earliest times of which any record exists in English history, there appear to have been assemblies of the nation, convoked to deliberate on occasions of great emergency. These, however, were less frequent after the Norman conquest, and it was not until the 49th of Henry III. (A. D. 1266), after the overthrow of Simon Montfort, earl of Leicester, that the people were regularly summoned by the king to send representatives to the great council of the nation. The crown, little apprehensive of the formidable character which the House of Commons was afterwards to assume, favoured all the steps of its early progress, hoping by those means to counterpoise the overbearing sway of the great barons, and at the same time to obtain supplies of money from the growing wealth of the people. The decline of the feudal system had for some time favoured such a system of policy. Baronies escheated by forfeiture or for want of issue had been subdivided; hence arose a class of men called minor barons, holding by knight's service; and these being too numerous and too poor to be all called to parliament, and to rank with the greater barons, were allowed to sit by representatives. Of these *knight's*, each *shire* was summoned to send two; writs to that effect being

addressed to the sheriffs of the several counties. The Cinque Ports probably about the same period sent their *barons*, and the cities and boroughs their *burgesses*. In early times these representatives appear to have considered attendance in parliament as a hardship rather than an advantage. It was expensive, and, from the imperfect police then established, often insecure; and the summons, being always the prelude to a demand for money, was by no means welcome. With the granting of supplies, however, was necessarily combined the right of petition, of stating grievances, and demanding guarantees; and these could not, by a sovereign pressed by various exigencies, be always denied. Thus the House of Commons continued to gain importance commensurate with that acquired by the body of the nation whom they represented; and at length, in a violent collision, they overthrew for a time both the sovereignty and the peerage. Since the re-establishment of the constitution, the third branch of the legislature has sustained no loss of the weight and influence which it then acquired.

1566. *The election of the Commons never rested on any principle of universal or even general suffrage*, excepting perhaps that of knights for each shire, who were certainly chosen by the general voice of the freeholders. As the kings, however, could only attain their objects by assembling the most powerful and influential of the people, they endeavoured to make an equal distribution of the right of election, so far, at least, as related to property and influence, at the time when such a measure was adapted to countervail the preponderance of the barons. In after-times, when seats in parliament came to be appreciated as conferring a desirable privilege, and as constituting a powerful check on the prerogative of the monarch, it would have been obviously irregular to have allowed to the king an arbitrary selection; and all parties adhered tenaciously to the rights conferred on them by early gift or long usage. This permanence of the elective franchise, amidst the local changes that ensued in the course of ages, gave rise to some very striking anomalies. Manchester, Leeds, and several other towns, which within the last century have become the commercial capitals of the kingdom, did not send a single representative; while places once important, but now dwindled into insignificance, returned each two members. Cornwall, at a period when the rest of the kingdom was poor and rude, enjoyed an abundant source of opulence in its tin mines, and retained a number of chartered boroughs, beyond all proportion greater than those of any other county. The places holding the right of election were in many instances so small, that what is called the patronage of them was easily acquired; and that patronage of course involved the advantage of nominating one or both candidates for the representation. These were called close boroughs, or, more reproachfully, rotten boroughs. Another anomaly consisted in a number of what were called treasury boroughs, the nomination of which rested with the administration. With the view of remedying these defects, the Reform Bill was passed, in 1832, after long discussion and opposition. By this bill fifty-six of the smallest boroughs were entirely disfranchised, and thirty were reduced from two members to one, while Weymouth and Melcombe Regis were reduced from four to two; a reduction was thus made of 144 members. In the room of these, twenty-two large places, — Manchester, Birmingham, Leeds, Sheffield, Greenwich, Sunderland, Devonport, Wolverhampton, Bolton, Blackburn, Bradford, Brighton, Halifax, Macclesfield, Oldham, Stockport, Stoke-upon-Trent, Stroud, and four districts of the metropolis, viz. Marylebone, Finsbury, Tower Hamlets, and Lambeth, — received each the right of electing two members; while twenty smaller towns, — Ashton-under-Line, Bury, Chatham, Cheltenham, Dudley, Frome, Gateshead, Huddersfield, Kidderminster, Kendal, Rochdale, Salford, South Shields, Tynemouth, Wakefield, Walsall, Warrington, Whitby, Whitehaven, and Merthyr Tydvil, — acquired the right of nominating one member each. At the same time twenty-seven counties acquired the power of sending each two additional members, and seven that of sending one additional member.

1567. *The representation of Great Britain now stands as follows:—*

English members for counties		-	-	143	
universities		-	-	4	
cities and boroughs		-	-	324	
					471
Welsh members for counties		-	-	15	
cities and boroughs		-	-	14	
					29
Scotch members for counties		-	-	30	
cities and boroughs		-	-	23	
					53
Irish members for counties		-	-	64	
university		-	-	2	
cities and boroughs		-	-	39	
					105
Making in all				-	658

1568. *The qualifications requisite for a member of the House of Commons*, in respect to property, are these:—A person to be eligible as member for a county must have a freehold or copyhold, or must have been mortgagee in possession at least seven years, of a clear estate of the value of 600*l.* per annum; and to be eligible for a city, borough, or other place, except the universities, of the value of 300*l.* per annum. The person so qualified is also to be of mature age, and must take the oaths imposed as indispensable to a member of the legislature. The disqualifications are very numerous, since among the persons who cannot sit in the House of Commons are judges, clergymen, persons holding certain offices under the crown, and persons having pensions under the crown during pleasure or for any term of years. Sheriffs of counties, and mayors, and bailiffs of boroughs, are ineligible in their respective jurisdictions; but a sheriff of one county is eligible as knight for another.

1569. *The qualifications required in electors* differ, as they relate to counties or to boroughs. In the election of county members every voter must have a freehold of the clear yearly value of forty shillings, over and above all rents and charges payable out of and in respect of the same, and must have been in the actual possession of it for twelve calendar months, unless it came to him within that time by descent, marriage settlement, devise, or promotion to a benefice in the church, or to an office. To these freeholders the new bill has added all persons holding property to the amount of ten pounds on copyhold, or on lease of not less than sixty years; and also those occupying lands or tenements for any period, at a rent of not less than 50*l.* per annum.

1570. *The qualifications of electors for cities and boroughs* were, previous to the present act, extremely various. The right of voting in different places resided variously in the freeholders, the corporations, the burgage tenants, and sometimes in the whole body of resident householders. The new act, however, admits only the simple qualification of occupying a house rated at not less than 10*l.* per annum. Those, however, who were freemen under the former system are still entitled to vote, although not possessed of the 10*l.* qualification, provided they reside within the borough.

1571. *The mode of proceeding to an election for a county and for a borough is nearly the same.* On a dissolution of parliament, writs, pursuant to a warrant from the king, are issued under the great seal, addressed to the sheriffs of counties, directing them to summon the people to elect two knights for each county, and one or two burgesses for each borough. To supply a vacancy while parliament is sitting, the warrant for the writ proceeds from the House of Commons. A certain day after, the date or *teste* of the writ is fixed for the election to commence; and on that day the candidate or candidates are put in nomination, at the place appointed, in the presence of the returning officer. In a county election, the sheriff or the under-sheriff is the returning officer; in a city or borough, the mayor or bailiff. If there be rival candidates put in nomination, the returning officer calls on the voters for a decision by a show of hands, after which the friend of any candidate, if dissatisfied, may demand a poll. The poll was formerly taken only at one place, and might last for fifteen days; but under the new act, the cities and counties are divided into districts, with separate booths, or polling-places, appropriated to each. The poll is allowed to continue only for two days, which must be successive, and it must close at four o'clock in the afternoon of the second day. Poll clerks attend, to record the names of the voters, and their accuracy is watched by inspectors nominated on each side. The returning officer who presides must, if required, oblige the candidates to swear to their qualifications. At the close of the election, or on the following day, the returning officer declares the names of the persons who have the majority of votes; and, unless a scrutiny be demanded, he forthwith makes his return.

1572. *The person thus elected and returned becomes the representative of the Commons of the united kingdom of Great Britain and Ireland, and not the delegate or agent of the particular place for which he takes his seat.* Petitions, complaining of undue elections, may be presented to the House of Commons; and rules for deciding upon them have been laid down in certain specific statutes. Against bribery, either by means of money, of entertainments, or of promises of places or favours, the strictest laws have been enacted; and, from recent examples, there is reason to believe that they will henceforward be rigorously enforced.

1573. *The duration of a Parliament* has, for more than a century, been extended to the term of seven years, from that of three, to which it was formerly limited. The king, however, has the power of dissolving parliament at any time, and he usually does dissolve it a year or two before the expiration of its term. He can also prorogue it at any time and for any period; and, as such prorogation concludes the session, it puts an end to all bills or other proceedings depending in either house, which must in the next session be again instituted, as if they had never been begun. Either house, or both houses, may adjourn of their own accord, and, at their meeting again, may take up the bills and other proceedings in the state of advancement in which they were left. A session of parliament usually commences in January or Fe-

bruary, and continues until June or July. If it commence before Christmas, an adjournment takes place for the holidays; the houses adjourn also at Easter for about fourteen days, and for shorter periods on any extraordinary occasion.

1574. *The attendance of members* is in general by no means full, and some of the ordinary though very important business of the nation is transacted in very thin houses. In fact, no means of enforcing attendance are adopted except a *call of the house*, which always precedes the discussion of very important questions, and is also required by act of parliament before taking into consideration any petition relative to a controverted election. Parties neglecting to attend on such call are liable to be taken into custody of the serjeant at arms, and to incur payment of the consequent fees, which amount to no inconsiderable fine. If forty members be not present at four o'clock in the afternoon, the speaker immediately adjourns the house to the day following, or to any other day which had been previously fixed for the next sitting. Every transaction in the house is the subject of a motion, of which previous notice is usually given by a member, and entered on a paper called the *order of the day*. Various motions, however, arising specially out of the business of the house, or from questions of privilege, may be made without notice. In the debates that occasionally ensue, much political knowledge is called forth, and sometimes much parliamentary eloquence displayed; yet the speeches, especially those of members in opposition, seem intended for the public rather than for the members, and of course call forth a corresponding tone in those of the speakers on the side of administration. The publication of debates, however, is so far from being authorised, that a standing order exists for the exclusion of strangers, which may at any moment be enforced by a simple intimation from any member to the speaker, that there are strangers in the house. The speaker proclaims that *strangers must withdraw*, and the gallery is instantly cleared. It is also cleared on every division, that the votes of the several members may not incur the imputation of being influenced by public opinion; yet lists of majorities and minorities are easily procured, and the part which any member has taken on any great public question becomes universally known.

1575. *The general business of Parliament* during a session consists in passing various public and private acts, and in making that provision for the service of the year, which the interests of the nation require. Proceedings of general or particular legislation may originate in either house, but the House of Commons hold the sole and exclusive right of granting aids and supplies to the crown. At the commencement of every session committees of the whole house are appointed; one called the *Committee of Supply*, to consider the amount required by the crown for the service of the army, navy, ordnance, and other departments; and the other the *Committee of Ways and Means*, to devise modes of raising, by taxes or loans, the sums which the house, on resolutions reported from the committee of supply, and agreed to, have granted to his majesty. In this committee of ways and means, the chancellor of the exchequer, in an exposition technically called the *Budget*, demonstrates to the house in detail that the sums voted are sufficient to justify the committee in imposing such taxes, or sanctioning such loans, as are then recommended. When the two committees are closed, the House of Commons pass a bill in which the several grants made in the committee of ways and means, by land-tax, malt-tax, loan, sinking fund, and other resources, are recapitulated, and directed to be applied to the services voted in that session in the committee of supply, specifying the particular sums granted for each service. The sums on account of the army, ordnance, militia, and foreign subsidies are in the bills of appropriation specifically applied to those services; but the sums voted for the navy are not appropriated specifically but generally, in consideration of circumstances arising out of the peculiar nature of that service.

1576. *Parliament have the sole right of making, altering, and amending all the laws of the kingdom*, and by their authority alone can taxes be imposed or levied. An annual vote of the House of Commons is requisite to maintain the land and sea forces at the degree of strength which is every year fixed and determined upon. By these and other privileges, the annual meeting of parliament is secured without any express stipulation to that effect. By withholding these annual votes they may testify their disapprobation of the measures of government, and even compel it to change its ministers; indeed, the principle has now become indisputable, that the minister who cannot rely on a majority of votes in parliament is disabled from conducting the affairs of the nation. Privileges so extensive seem at first sight to threaten with annihilation the royal prerogative, and establish the absolute dominion of the two estates in parliament. In fact, however, the case is otherwise. The power possessed by the king of appointing to all offices civil and military, secures to him immense influence. If the members of parliament have nothing to fear, they have so much to hope, that a great proportion of them are thoroughly disposed to support the measures of the crown. Many of the peers, and of their relatives and connections who hold seats in the other house, consider the interests of the sovereign as in some measure identified with their own: and their votes, with those on which the Treasury can always calculate, generally contributes to maintain the equipoise of parties, or rather to secure the preponderance of that which is entrusted with the conduct of affairs. Some politicians, indeed, entertain great deference for the warning of a late eminent statesman, that the influence of the crown has increased, is increasing, and ought to be diminished; yet, on examination, it will probably be found that this influence

affords no great cause of alarm, and that the odium of increased taxation, the publicity of debate, the liberty of the press, and the independence of the tribunals, constitute substantial guaranties, which ought to relieve the nation from every reasonable apprehension for the loss of its liberties.

1577. *The Privy Council* holds a primary influence in directing the civil government of the kingdom. It is composed of eminent persons, appointed by the king, without restriction as to number, who are bound by oath to advise their sovereign to the best of their judgment with all the fidelity and secrecy which their station prescribes. The king may declare to, or conceal from, his privy council, whatever he thinks fit; and by constitutional usage he has a select council out of their number, commonly called the Cabinet Council, with whom his majesty determines such matters as are most important, and require the utmost secrecy. The king with the advice of his privy council publishes proclamations binding on the subject; but they are to be consonant to, and in execution of, the laws of the land. The power of the council is, to enquire into all offences against the government, and to commit the offenders to safe custody for trial in some of the courts of law; but persons so committed are entitled to their *habeas corpus* as much as if they had been committed by an ordinary justice of the peace. The privy council is a court of appeal in plantation and admiralty causes, which arise out of the jurisdiction of the kingdom, as also in cases of idiotcy and lunacy. When questions arise between two colonies respecting the extent of their charter, "*the king in council*" exercises original jurisdiction in them, on the principles of feudal sovereignty; he also determines, on the same principles, the validity of claims to an island or province founded upon grant from the king or his ancestors. But from all the dominions of the crown excepting Great Britain and Ireland, an *appellate* jurisdiction, in the last resort, is vested in the *privy council*. The judicial authority is exercised in a committee of the whole privy council, who hear allegations and proofs, and make their report to *his majesty* in council, by whom judgment is finally given. The dissolution of the privy council depends on the pleasure of the king, who may at his own discretion discharge any member, or the whole of them, and appoint another council. By the common law it is dissolved *ipso facto* on the demise of the crown, but by the statute 6 Anne, c. 7. it is to continue six months after the demise, unless sooner determined by the successor. Any natural-born subject of England is capable of being a member of the privy council, taking the proper oaths for security of the government and test for the security of the church. A privy counsellor, if he be only a private gentleman, is styled *right honourable*, and takes precedence of all knights, baronets, and the younger sons of all barons and viscounts.

1578. *A cabinet council* is not, strictly speaking, recognised by the constitution, but by usage it is regarded as a body selected by the sovereign to conduct the business of the state; and the members composing it are held to be the responsible advisers of the crown. This responsibility must rest on their honour: for it is by no means evident that any advice could be legally traced to them as confidential servants of the crown; and they are not liable to impeachment in their simple capacity as privy counsellors, which they generally share with others who are opposed to them in opinion on matters of policy. The responsibility, however, is imposed by the constitutional maxim that "*the king can do no wrong*;" and it is virtually acknowledged by the act of resignation generally adopted by the members of a cabinet, when the course of policy recommended by them is not approved by the king. The cabinet council usually consists of those ministers of state who exercise the most important and arduous functions of the executive authority; their number and selection depend only on the king's pleasure; and each member receives a summons for every attendance. Though this body, as constituting what is essentially *the government*, be composed principally of officers of state; yet a privy counsellor selected by the king as a member of his cabinet council, may hold his seat as such, without accepting any particular office. The officers of state are those enumerated in the following lists:—

1579. *Officers of State forming the Cabinet.*

First Lord of the Treasury.	Secretary of State for Colonies and War.
Lord Chancellor.	Chancellor of the Exchequer.
Lord Privy Seal.	First Lord of the Admiralty.
President of the Council.	Master-general of the Ordnance.
Secretary of State for the Home Department.	President of the Board of Control.
Secretary of State for the Foreign Department.	Chancellor of the Duchy of Lancaster.

Officers of State not of the Cabinet.

Lord Chamberlain.	Vice-President of the Board of Trade.
Lord Steward.	Postmaster General.
Master of the Horse.	Lieutenant-General of the Ordnance.
Secretary at War.	First Commissioner of the Land Revenue.
Treasurer of the Navy.	Attorney-General.
President of the Board of Trade.	Solicitor-General.
Paymaster of the Forces.	

1580. *Ireland.*

Lord Lieutenant of Ireland.	Vice-Treasurer.
Lord Chancellor.	Attorney-General.
Commander of the Forces.	Solicitor-General.
Chief Secretary.	

1581. *That officer of state who holds the appointment of First Lord of the Treasury, is by eminence the minister.* In the event of a change of ministry, the person who is directed by the king to form another, receives, in such royal command, an implied offer of that high office, and is generally placed at the head of the administration. The first lord of the treasury, that is, the first of the five lords commissioners for executing the office of lord high treasurer, possesses most of the powers formerly held by the lord high treasurer, and is sometimes, though not invariably, chancellor and under treasurer of the exchequer. That the chief direction of the government should be vested in the minister to whom the revenue is confided, appears perfectly consistent with the interests of a country in whose financial affairs all the civilised world is concerned, and whose domestic and foreign policy must chiefly depend for success on the ability and prudence with which those affairs are conducted.

1582. *The finances of the United Kingdom constitute a subject too extensive to be exhibited in all its details within the limits prescribed by the general plan of this work.* We shall, therefore, confine ourselves to a concise summary, in reference to which it may be expedient to offer a few introductory observations. The revenue applicable to the general purposes of the state is, with a very trifling exception, derived entirely from taxes. In the course of the last century it increased to an amount unparalleled in the history of any other country; but in consequence of the wars in which Great Britain was engaged with little intermission until the year 1815, it did not keep pace with the expenditure, and an enormous debt was gradually contracted, the interest on which occasioned a correspondent increase of taxation.

1583. We are indebted to Mr. M'Culloch (*Commercial Dictionary*, art. FUNDS) for the following account of the progress of the *national debt*, from the Revolution to the present time:—

	Principal.	Interest.
	£	£
Debt at the Revolution in 1689	664,263	39,855
Excess of debt contracted during the reign of William III. above debt paid off	15,730,439	1,271,087
Debt at the accession of Queen Anne in 1702	16,394,702	1,310,942
Debt contracted during Queen Anne's reign	37,750,661	2,040,416
Debt at the accession of George I. in 1714	54,145,363	3,351,358
Debt paid off during the reign of George I. above debt contracted	2,053,125	1,133,807
Debt at the accession of George II. in 1727	52,092,238	2,217,551
Debt contracted from the accession of George II. till the peace of Paris in 1763, 3 years after the accession of George III.	86,773,192	2,634,500
Debt in 1763	138,865,430	4,852,051
Paid during peace	10,281,795	380,480
Debt at the commencement of the American war in 1775	128,583,635	4,471,571
Debt contracted during the American war	121,267,993	4,980,201
Debt at the conclusion of the American war in 1784	249,851,628	9,451,772
Paid during peace, from 1784 to 1793	10,501,380	243,277
Debt at the commencement of the French war in 1793	239,350,148	9,208,495
Debt contracted during the French war	608,932,329	24,645,971
Total funded and unfunded debt, 5th of January, 1817, when the English and Irish Exchequers were consolidated	848,282,477	33,854,466

1584. Since 1817, a deduction has been made of about *sixty* millions from the principal of the debt, and about *five* millions from the annual charge on its account. This diminution has been principally effected by taking advantage of the fall in the rate of interest since the peace, and offering to pay off the holders of different stocks, unless they consented to accept a reduced payment.

1585. *The system of funding*, by which the debt has been rendered national, rests on the principle of assigning for the amount of a loan, an equivalent amount of nominal capital, bearing interest charged on the national revenue in half-yearly payments called dividends, or of terminable annuities also payable half-yearly. Annuities granted for an indefinite period are called *redeemable debt*, being redeemable at the option of government when at par; those granted for a limited period are called *irredeemable debt*; they exist only for a certain number of years, and a portion of the capital is annually absorbed in the interest. The funds are respectively designated according to the rate per cent. they bear; and the share which a public creditor holds in any of them, being transferable by sale under the name of *stock*, they constitute a kind of circulating capital. The prices of stock vary according to the fluctuations of public opinion relative to political affairs, and are liable to be influenced by other causes, so that their rise and fall afford a constant subject of commercial speculation.

1586. *The rate of interest* granted on certain portions of the national debt, though nominally lower than that of five per cent. allowed by law, has been rendered advantageous to the lender by being charged on a larger amount of nominal capital than the sum borrowed. Loans have been made in funds at four and five per cent., but the greater part has been made in a fund bearing three per cent. interest on the nominal capital, and commonly called the *three per cent. consolidated annuities*. The prices of these and other annuities constituting the *redeemable debt* are rated according to the money value of one hundred pounds on such stock; terminable annuities according to the number of years' purchase which they are supposed to be worth. Thus, on a particular day the market price of three per cent. consols may be eighty-four and three quarters, the value of 100*l.* in that kind of stock being 84*l.* 15*s.* And bank long annuities may be rated at nineteen and one eighth; that being the number of years' purchase at which they are then valued.

1587. *Particular taxes* were, at an early period of the funding system, appropriated to defray the interest of different descriptions of debt; but in the year 1786, the whole were collected into one fund, called the *Con-*

solidated Fund. The particular branches of revenue included in it were the *customs* (with the exception of a certain amount applicable to other public services), the *excise*, the *stamps*, the *land* and *assessed taxes*, and the *post-office*. To this fund are applicable various minor imposts, and monies arising from other resources, specified in the annual accounts.

1588. A *sinking fund* for the gradual reduction of the debt had been formed by Sir Robert Walpole in 1716, but had been so frequently encroached upon, that in the course of half a century, it had not extinguished above fifteen millions. Its revival formed part of the financial arrangements of Mr. Pitt in 1786. Out of the aggregate of the taxes applicable to the consolidated fund, government then pledged itself, whatever might be the proportion of revenue to expenditure, that one million annually should be paid to the new commissioners for the reduction of the national debt. To this annual million were added the amount of government annuities as they successively expired, and the interest of such stock as was annually redeemed. The sinking fund, thus constituted, excited great hopes among the people, which were strengthened in 1792, when Mr. Pitt obtained an act of parliament, declaring, that besides a provision for the interest of any loan that might be thenceforward contracted, taxes should be imposed for a sinking fund of one per cent. on the capital stock created by it, which should be exclusively employed in the liquidation of such particular loan; and that no relief should be afforded to the public from the taxes which constituted the one per cent. sinking fund, until a sum of capital stock, equal in amount to that created by the loan, had been purchased by it. That being accomplished, both the interest and the sinking fund were to be applicable to the public service. It was calculated that, under the most unfavourable circumstances, each loan would be redeemed in forty-five years from the period when it was contracted. The provisions in this act, and in the former act of 1786, were altered by subsequent enactments; but, by an act passed in 1813, those alterations were rescinded; and it was provided first, that, as a sum equal to the debt of 1786, and bearing an interest nearly equal to the interest of that debt, was then vested in the hands of the commissioners, the debt of 1786 should be declared discharged as soon as the interest of the debt redeemed should become fully equal to that debt; the sums appropriated to its interest and sinking fund applied to the charge of future loans, and no new taxes imposed for interest and sinking fund of those loans, till the same should amount to a sum equal to the interest of that considered as released. Secondly, that, instead of applying the one per cent. sinking fund on each loan to the separate discharge of that loan, the whole funds of that kind united should be applied to the discharge of the first contracted loan, and successively to the redemption of all the loans contracted since 1792; the whole sinking fund created in 1786, or subsequently, being continued for the redemption of all debts then existing or to be created. The system established by this act continued until March, 1823, when an act of parliament was passed, directing that on the 5th of April of that year, all payments out of the consolidated fund to the commissioners for the reduction of the national debt should cease, all stock in their names be cancelled, and that in future the annual sum of five millions shall be payable quarterly to the commissioners, and set apart for the reduction of the debt, not to be infringed upon until the accumulation of this sum shall amount to one hundredth part of the debt then existing: at present, however, the sinking fund is declared to be the excess of income over expenditure, whatever that may be. In 1830 it amounted to 2,792,707*l.* 14*s.* 0*d.*

1589. On the *consolidated fund* are likewise charged the annuities for forty-five years, created in the year 1822, for the purpose of apportioning the burden occasioned by the military and naval pensions and civil superannuations (collectively called the *Dead Weight*), amounting to 5,000,000*l.*, into equal annual payments. The original intention was to contract with parties who might be willing to engage to pay into the exchequer within forty-five years the sum wanted, for a fixed amount of annuity for forty-five years; but no capitalists being found to accept these terms, it was agreed, instead of assigning the fixed annuities to any corporate body, or to private individuals, that they should be vested, namely, 2,800,000*l.* terminable at the end of forty-five years, and charged upon the consolidated fund, in trustees appointed by parliament; payable at the exchequer half yearly (viz. October 10. and April 5.), and to cease in April, 1867. In March, 1823, a portion was sold to the Bank of England by the trustees, on condition that the bank should undertake the payments to be made in pursuance of the act, from the 5th of January, 1823, to the 5th of January, 1828, upon the transfer to the bank of an annuity of 585,740*l.*, to commence from the 5th of April, and to continue for the term of forty-five years. The total amount of payments undertaken to be made by the bank in consideration of the said annuity is 13,089,419*l.*

1590. Besides the funded debt, there is generally a considerable amount in *exchequer bills*, *navy bills*, and *ordnance bills*, denominated the *unfunded* or *floating debt*. Exchequer bills are issued in consequence of acts of parliament, for obtaining part of the money required for public service. They are sometimes granted on the credit of supplies for the current year, and the produce of the annual taxes is in this way often anticipated. Sometimes they are charged on the supplies of the following year; and in time of war, a large sum to be thus raised is generally authorised by a vote of credit previous to the rising of parliament. New exchequer bills are often issued in discharge of former ones; and it has frequently been found necessary to *fund* them, by granting capital in some of the stocks on certain terms, to such holders as are willing to accept them. Exchequer bills are issued for 100*l.*, 500*l.*, 1000*l.*, and upwards, but none for less than 100*l.*; and they bear interest at two-pence a day for every 100*l.* After being in circulation they are received in payment of taxes or other debts due to government, and sometimes they are paid off pursuant to previous notice by advertisement. The daily transactions between the bank and the exchequer are chiefly carried on by bills of 1000*l.* each, which are deposited by the bank in the exchequer, to the amount of the sums received by them on account of government; they remain in the exchequer as pledges or securities, of course bearing interest until the advances on which the bank first received them are paid off.

1591. The *expedient of temporary war-taxes* for the purpose of raising a large proportion of the supplies within the year, has been lately adopted to a great extent. The most considerable impost of this kind during the late war was the property tax, which produced during the last two years of that war more than fifteen millions per annum. Of the total sum of eleven hundred millions expended during twenty-three years from the beginning of 1793 to 1816, the amount added to our permanent debt was 460,000,000*l.*, so that the aggregate of the supplies raised within the year amounted, for the whole war, to 640,000,000*l.*; "a surprising sum," observes Mr. Lowe, in his valuable work on the State of England, to be obtained by a mode of taxation almost unknown in foreign countries, and carried in former wars to a very limited extent among ourselves. During each of the last two years of the war, viz. 1814 and 1815, the taxes raised from Great Britain alone, exclusive of Ireland, exceeded seventy millions, and a loan of forty millions with the aid of exchequer bills and other expedients made up the unprecedented amount of one hundred and twenty millions of annual outlay. Since the restoration of peace a very considerable reduction of taxation has been effected. The whole of the property tax, part of the assessed taxes, the duties on salt, beer, leather, coals, candles, and printed goods have been taken off. In 1831 the net produce of all the branches of revenue had been reduced to 54,644,703*l.*, a sum still without parallel in the finances of any other country.

1592. The following *Parliamentary Paper* (No. 725. Sess. 1832) gives, in a brief compass, the clearest and most satisfactory details that can be desired of the public income and expenditure of the United Kingdom, during each of the three years ending with the 5th of January, 1832: —

1593. PUBLIC INCOME AND EXPENDITURE

Heads of Income.	INCOME.

1595. *Number of persons deriving incomes from the funds.* It appears from the subjoined account, that in 1830 (and the number has not sensibly varied since), 274,823 dividend warrants were issued to persons deriving incomes from the funds. In point of fact, however, the number of persons dependent upon the funds for support is much greater than appears upon the face of this account: for the dividends upon the funded property belonging to the Equitable and other insurance companies, the various banking companies, and other public establishments, are all paid upon single warrants, as if they were due to so many private individuals, whereas they are really paid to these individuals only because they act as factors or trustees for a vast number more.

1596. Account of the Total Number of Persons to whom a Half Year's Dividend on Three per Cent. Consols became due on 5th January last; specifying the Number respectively of those whose Dividend for the Half Year did not exceed 5*l.*, 10*l.*, 50*l.*, 100*l.*, 200*l.*, 300*l.*, 500*l.*, 1000*l.*, 2000*l.*, and the Number of those whose Dividend exceeded 2000*l.*; a like Account of Dividends on Three per Cent. Reduced, payable on the 10th of October last; a like Account of the Dividends on Three and a Half per Cents., payable on the 10th of October last; a like Account of Dividends on Four per Cents., payable on the 10th of October last; a like Account of the Dividends on Long Annuities, payable on the 10th of October last; a like Account of the Dividends on New Four per Cents., payable on the 5th of January last; and a like Account of the Dividends on Three per Cent. Annuities, anno 1726, payable on the 5th of January last; with a Total of the Number of Persons under each Head. (*Parl. Paper*, No. 41. Sess. 1830.)

1597 *Portion of revenue contributed by each division of the empire.* There are no means by which it is possible to assign to each portion of the empire what may be considered its proper share of the total expenditure. But the following Table shows how much each contributes to the revenue:—

Return of the Revenue collected in 1831, in England, Wales, Scotland, and Ireland, respectively; distinguishing the Customs, Excise, Stamps, and Assessed Taxes.

Places.	Customs.			Excise.			Stamps.			Land and Assessed Taxes.			Post Office.			Total.

1598. *The customs and excise form the two main branches in the collection of the revenue; the former relating to goods imported, the latter to those produced and manufactured within the country.* This division was essentially modified by Mr. Pitt, who, finding the excise survey the most effective and economical, transferred to it wine, tea, spirits, and tobacco, the most productive branches of imported goods. Under a late parliamentary commission, however, those branches have been again transferred to the customs, and the original distinction of the two branches has been completely re-established; it being considered that the new regulations introduced into the Board of Customs will obviate former objections. Under the same commission great exertions have been made to regulate and economise all the revenue departments. Those of the three kingdoms have been incorporated together, and each department ruled by one general board resident in London. Among the most important accommodations to trade, established by Mr. Pitt, is the *bonding system*, by which the goods of merchants are warehoused under the joint custody of the proprietor and of government; payment of duty not being demanded until a sale is effected. This has been also extended to British spirits.

* The accounts of the Stamp Department do not afford the means of distinguishing the amount of revenue received in Wales.

1599. *The navy* is the force on which Great Britain mainly relies for maintaining her own independence and her ascendancy over foreign nations. By it she has acquired the sovereignty of the seas, and the advantages, which that sovereignty confers, of securing her possessions in the most distant quarters of the globe, of protecting her commerce, and sustaining the exertions of her armies during war. The achievements by which she has won this arduous and well merited ascendancy are alike honourable to the heroes who commanded her fleets, and to the brave men who fought under them; especially in the late war, when she triumphed over the navies of Europe, united under the direction of France. The matchless valour of British seamen, displayed on that and on other occasions, is the more to be admired, since a large proportion of them are procured by means which only extreme necessity can justify; we allude to impressment, the only mode of conscription practised in this country, if conscription that can be called, which is attended with circumstances so violent and irregular. It appears, however, to have been discontinued, except in urgent cases, when a sudden augmentation of the naval force is required. During the most active period of the last maritime war, the number of seamen in employment amounted to 140,000; and there were in commission 160 sail of the line and 150 frigates, with 30,000 marines. Before the termination of the contest, however, such was the humbled condition of the foreign navies opposed to us, that our superiority was maintained with a much smaller force. The vote for the sea service of 1815 was limited to 55,000 seamen and 15,000 marines. After the ratification of peace, the establishment was rapidly reduced; in 1817 it amounted to no more than 13,000 seamen and 6000 marines. This number, however, was considered too small to maintain the proper authority of Great Britain, in the then disturbed state of affairs on the Continent. The estimate for 1831 comprehended 22,000 seamen and 10,000 marines. The pay of these men, at 2*l.* 12*s.* a month, amounts to 1,081,000*l.*; their subsistence, at 1*l.* 9*s.* a month, to 603,000*l.*; which, with the cost of stores, and allowance for wear and tear, raised the regular current expense to nearly 2,000,000*l.* The building and repair of vessels, the charges of the dock-yards, pay of officers connected with the navy, pilotage, packets, medical establishments, and a variety of other items, amounted to about an equal sum. The amount of 1,457,000*l.* in half pay, pensions, and superannuations, was entailed by the enormous establishment of the late war, and was in a gradual state of diminution. These charges, with about 231,000*l.* for freights and other extraordinaries, made up the sum of 4,657,000*l.* as the entire navy estimate for the year 1831.

1600. *The British army* always fought with glory, and maintained a reputation for valour rarely equalled and never surpassed by that of any other nation. Early in the last century, under Marlborough, it took the lead in the great European confederacy, and was mainly instrumental in humbling the overgrown alarming power of Louis XIV. In subsequent wars on the Continent, Great Britain fought as an auxiliary, and often against unequal numbers. Her troops never lost their reputation; but the cause in which they were engaged, however meritorious, was often unfortunate. This ill success particularly marked their efforts in the outset of the French revolutionary war, when the levies *en masse*, called forth by the republican government, constituted a force too numerous, active, impetuous, and enthusiastic to be resisted by the regular armies of Europe. So distressing were the reverses of the British arms at that period, and so mortifying when contrasted with our naval glories under Howe, Duncan, Jervis, and Nelson, as to create a very general opinion that Great Britain ought to relinquish further exertions on the Continent, and reserve her resources exclusively for maritime warfare. The campaign in Egypt rekindled the hopes of military glory; but a considerable period elapsed ere they could be strengthened by opportunities of more extended warfare. At length the patriotic and inflexible resistance of the Spanish nation to the foulest usurpation on record, opened as fair a field as could be desired for an army comparatively little inured to active warfare;—a peninsula, where the land forces of a power holding the supremacy of the sea could rely on the co-operation and support of their fleets, and where an invading enemy might be harassed in small engagements, until the developement of his tactics rendered it less difficult to defeat him in greater battles. The campaigns in the peninsula, and the unexpectedly rapid success of the northern alliance, gradually drew on Great Britain to the full *production* of her military energies on the Continent; and they terminated the war by a victory at Waterloo, under the Duke of Wellington, which may rank among the most brilliant and memorable achievements of the British arms. The military force of the nation, at this time, amounted to 200,000 regular troops, exclusive of about 100,000 embodied militia, a large amount of local militia and volunteers, to which might also be added a number of regiments employed in the territories of the East India Company, and in its pay. As the militia, however, did not leave the kingdom, and a great part of the regular troops was dispersed in colonies and garrisons; the force in Flanders, at the outset of this memorable campaign, scarcely amounted to 50,000 men; forming, indeed, a central host, round which rallied an equally numerous force composed of Germans, Dutch, and Flemings. After the abdication and exile of the enemy of Europe, which were the consequences of that decisive victory,

a rapid reduction of our military establishment was effected. The militia were disembodied; the regular force was reduced, in 1817, to 92,000 men, and in 1819 to 69,000. Circumstances which afterwards arose in Europe and in our own colonies led to successive augmentations; and in 1831 the estimates were for 88,000 men; of whom 74,000 were infantry of the line, 5700 foot guards, 1300 dragoon guards, 7000 dragoons. This was independent of 18,000 men employed in India, and paid by the Company. The charge for these forces was 6,381,000*l.*; but of this sum 3,240,000*l.* consisted of half-pay, retired allowances, pensions, and other charges consequent on the former immense establishment. Of the vast host of volunteers called forth by the menaced invasion during the war, some corps of yeomanry cavalry were all that remained, and most of these have been recently disbanded, their services being no longer deemed requisite to maintain domestic tranquillity. We now proceed to trace the internal regulations on which the preservation of that tranquillity chiefly depends.

1601. *The laws of England, established during ten centuries of legislation, constitute the most extensive, if not the most perfect system of jurisprudence which human wisdom has ever constructed.* The municipal law, justly estimated as the most valuable inheritance of the people, is divided into two kinds, the *unwritten* or common law; and the *written* or statute law. The common law derives its force from long and immemorial usage; and its evidences exist in the records of the several courts of justice, as well as in books of reports and judicial decisions. It includes not only the system by which the ordinary courts of justice are guided and directed; but certain portions of the ancient civil and canon laws which are used in the ecclesiastical courts, the military courts, the court of admiralty, and the courts of the two universities. The written laws are those made by the king, lords, and commons, in parliament assembled; they are judicially called *Statutes*, and are either *declaratory* of the common law, or *remedial* of some of its defects. The statutes are also distinguished as either general or special, public or private.

1602. *The high court of parliament, independently of its legislative functions, is the supreme court of judicature in the kingdom.* The House of Lords exercise jurisdiction in civil causes, upon appeals or writs of error from the inferior courts, and in criminal questions, when brought before them by presentment of the House of Commons, in the form of an impeachment.

1603. *The high Court of Chancery derives its name from the judge who presides in it, and who is called the Lord High Chancellor.* It has two distinct tribunals: the one ordinary, being a court of common law; the other extraordinary, being a court of equity. From the ordinary or legal court issue all original writs that pass the great seal, all commissions of charitable uses; as also of bankruptcy, idiotcy, and lunacy; for such writs it is always open to the subject, who may there demand and have them, *ex debito justitiæ*. In the extraordinary court, or court of equity, the chancellor exercises a most extensive jurisdiction, determining causes beyond the reach of the ordinary tribunals, and others in which reason and justice require that the rigorous application of the rules of common law should be mitigated. These decisions emanate from the judgment of the lord chancellor alone. The affairs of this court, however, having been found too extensive for one man to execute, an assistant judge has been appointed, pursuant to an act passed in the 53 Geo. III. He is called Vice-chancellor of England, and has power to hear and determine all causes depending in the court; all his decrees are valid and effectual, subject, however, to *reversal* by the lord chancellor, and not to be enrolled until signed by him; nor are they to discharge, reverse, or alter any decree of the lord chancellor or of the Master of the Rolls. The vice-chancellor holds his office during good behaviour. The Master of the Rolls, who ranks next to him in dignity, and holds his office for life, acts in a judicial capacity as assistant to the lord chancellor, and also hears and determines causes on certain appointed days; but his orders and decrees cannot be enrolled until signed by the lord chancellor, who has the power to discharge or alter them. The masters in chancery are twelve in number, including the Master of the Rolls, who is their chief, and also including the Accountant-General. They are assistants and associates of the lord chancellor and the master of the rolls, and sit with them in court by turns, two at a time. To the masters in chancery are directed references touching accounts, and matters of practice, upon which they make their reports. They also administer oaths to those who swear to answer; and take affidavits and acknowledgments of deeds and recognisances. The increase of business in this court has of late years been astonishing. In 1756, the property of suitors in chancery amounted to only 2,264,000*l.*; in 1776, to 6,602,000*l.*; in 1796, to 14,550,000*l.*; in 1816, to 31,950,000*l.*; and in 1826, to more than 40,000,000*l.* Formerly each master in chancery kept in his hands all monies paid into court in the causes referred to him; but, to remedy certain inconveniences thence arising to suitors, an act of parliament was passed appointing an accountant-general. On the passing of this act, the masters made up their accounts with him, and thenceforward have paid into the Bank of England all monies remaining in their hands, to be placed to his account, and have also transferred to him all securities which they held in trust for suitors. The accountant-general cannot, however, meddle with the actual receipt and custody of the suitors' money and effects, but only keep

the account with the bank. The governor and company of the Bank of England are answerable for such monies, and not the accountant-general.

1604. *The Court of King's Bench is the supreme court of common law in the kingdom.* It takes cognisance both of criminal and civil causes; the former in what is called the crown side or crown office; the latter in the plea side of the court, where, by a fiction of law, actions are brought which may render a defendant answerable to the King as well as to the injured party. The Court of King's Bench is also a court of appeal, into which may be removed, by writ of error, determinations of all the courts of record in England. The court consists of a chief justice, and three *puisné* judges, who are, by their office, sovereign conservators of the peace and supreme coroners of the land.

1605. *The Court of Common Pleas takes cognisance of all civil actions depending between subject and subject.* Many questions, however, may, by legal contrivances, be brought into this or into the Court of King's Bench at the option of the parties; and the emulation thus excited is considered to be one chief cause of the eminence to which these courts have attained. The Court of Common Pleas consists of a chief justice, and three *puisné* judges.

1606. *The Court of Exchequer has jurisdiction both in law and equity.* In it are tried all questions relating to the revenue, and, by fictions of law, various civil actions and personal suits. The judges are four; a chief baron and three *puisné* barons.

1607. *Trial by jury*, an institution coeval with the origin of the constitution, and justly valued by the people as the bulwark of their liberties, is employed in all cases between the crown and the subject, in all criminal cases, and in all those for which damages are awarded. The jury in England consists of twelve persons, whose verdict must be delivered by their foreman as unanimous, or, in the technical phrase, as *agreed upon*.

1608. *Courts of Assize and Nisi Prius are ordained as auxiliaries to the superior courts at Westminster for the trial of causes in every county in England, twice a year in most counties, once a year in others.* The counties are comprised in six circuits: 1st, the Home Circuit; 2d, the Midland; 3d, the Norfolk; 4th, the Oxford; 5th, the Northern; and 6th, the Western Circuit. These circuits are supplied by the twelve judges, two being appointed to each. They sit by virtue of five several authorities: the commission of the peace; a commission of *oyer and terminer*; a commission of general gaol delivery; a commission of assize to take the verdict of a peculiar jury summoned for the trial of landed disputes; and a commission of *nisi prius*. This last is a consequence of the commission of assize, the judges being, by statute 13 Edw. I. c. 30., empowered to try questions of fact at Westminster by a jury returned from the county wherein the action arises, *nisi prius, unless before the day fixed, the judges of assize come into that county, which they are sure to do in the vacation preceding each Easter and Michaelmas term.* In these courts, the senior or superior judge generally sits on the crown side for the trial of criminals, and the junior or inferior judge on the *nisi prius* side, for the decision of cases of property.

1609. *A Court of General Quarter Sessions of the Peace, held in every county once in every quarter of a year is the most important of the minor tribunals.* Its jurisdiction extends to all felonies and trespasses; but murders and other capital felonies are usually remitted for more solemn trial at the assizes. It also takes cognisance of offences relating to game, and of other misdemeanors. The records of the sessions are delivered for preservation to the *custos rotulorum* of the county. The sheriff's tourn is also a court of record, held twice a year at some place within the county. The court leet or view of frank-pledge is a court of record held once a year, and not oftener, within a particular hundred, lordship, or manor, before the steward of the leet, a Saxon term synonymous with the German *leute*, the people. It is the King's court granted by charter to the lords of those hundreds or manors. Its original intent was the view of the frank-pledge, or freemen within the liberty, who, according to the institution of Alfred, were all mutually pledges for the good behaviour of each other. The common objects of this court and of the sheriff's tourn are, the preservation of the peace, and the chastisement of various minute offences against the public welfare. In aid of these, and other institutions tending to the maintenance of order and tranquillity throughout the country, subordinate magistrates are appointed in each county, under the name of justices of the peace. They hold special commissions from the king, and are empowered to suppress riots and affrays, to take securities for the peace, and to commit felons and inferior criminals. Their jurisdiction is enforced by constables and other subordinate officers. The person who presides over them is the *custos rotulorum*, who is generally the lord lieutenant of the county, nominated by the king's sign manual. Thus the sovereign authority extends through just gradations to every part of the political fabric, and perpetuates the characters impressed upon it by the wisdom and virtue of its immortal founder.

SECT. V. *Productive Industry.*

1610. *The productive industry of England, at this moment, far surpasses that of any other country, either ancient or modern.* Her fabrics clothe the most distant nations; her vessels traverse alike the polar and equatorial seas. This pre-eminence has been attained too without any sacrifice of national spirit and energy; and the issue of the late war fully refuted the aspersion thrown on the British, as a mere nation of shopkeepers.

1611. *During the early periods of her history, England could not be said to have attained to a state of prosperity.* The nation, indeed, was always brave, but poor; the ground was rudely cultivated by serfs dependent on their feudal lords; its wool was purchased by the Flemings, and returned in a manufactured state for the clothing of the indolent natives. The downfall of the feudal power; the civil and social advantages which the people acquired under the last Henries; and, above all, the spirit of enterprise diffused among them under Elizabeth, gave a great impulse to commerce and industry. It was not, however, till the era of the Revolution, that the nation entered upon that grand career of prosperity, in which she has ever since proceeded with accelerated activity.

1612. *Agriculture, as the greatest and most essential source of human wealth and comfort, must always claim pre-eminence over the other branches of human industry.* For two or three centuries the English tenantry have been an independent and substantial race. Such had been the progress of agriculture, that, even in the middle of the last century, England had become a regular grain-exporting country. Still, fifty years ago, the practice of this important art was comparatively cumbrous, costly, and unproductive. It had not become an object of enquiry to men of liberal minds; it was left to be carried on by the common farmer, in a mechanical manner, according to the unimproved routine of his forefathers. The number of labouring cattle, both horses and oxen, employed in a farm, was superabundant in the extreme; manure was very carelessly collected; the green crops were not generally hoed, and artificial grasses were little known. The management of cattle was generally so bad, that Mr. Young conceived "that two pounds were lost upon every cow; while sheep might have

generally yielded a greater profit by three fourths; and the management of swine was perfectly execrable." In the general economy of the country, a neglect of enclosure prevailed; a large extent consisted of commons, covered with miserable herds, which the neighbourhood turned out to pasture; and a great part of the eastern coast, consisting of fens and marshes, was unhealthy and unfit for cultivation. Since that time, a complete change has taken place in all these respects. The greatest nobles and statesmen have vied with each other in their zeal for the promotion of agriculture. Prizes, exhibitions, and other institutions calculated to excite a spirit of improvement, have been established on a great scale. Even royal patronage was extended to this most useful of arts, and a board was formed under public auspices for its promotion. An extraordinary impulse was also given by the scarcity at the close of the eighteenth century; when the continental ports were closed, and grain rose to an unprecedented price, from which it has since been reduced, indeed, but not to its former rate. The old routine system was, after that crisis, broken up, and every exertion made to augment the products of the soil. Commons were enclosed, marshes drained, grasses of the most useful species cultivated, and every process that multiplied experiments had proved to be advantageous, introduced. Particular attention was bestowed in improving the breed of cattle and sheep; and for the accomplishment of this purpose, the best species were imported from abroad. At the same time, economical farming was greatly studied; the disproportionate number of horses and oxen was reduced; and machinery, particularly the threshing-machine, came into general use. Thus a great augmentation took place in the produce of the soil; still greater in the profit of the farmers, and much the greatest in the rent of the landlord, which, in many instances, was more than tripled. The reduced prices, however, which have ultimately been the result of this augmented production, have, at last, rendered it difficult to support the great advance in this last particular.

1613. *The natural fertility of England* is not equal to that of the countries in the south of Europe. Her wheat is not so fine, and she produces no wine. Her pastures, however, are richer; and her soil is capable of yielding all the valuable kinds of grain in abundance, and of good, if not superior quality. These natural advantages, improved by her extraordinary industry, raise the agricultural products of England to a much greater amount than those of any other country in Europe.

1614. *The surface of England* has been stated by official authority at thirty-seven millions of acres. About half a million is occupied by roads; and if we also make allowance for waters, natural and artificial, &c., we may probably have to deduct two millions from the part which forms the proper subject of agriculture. Of this, Mr. Young observes, "Half is under the plough, and half devoted to pasturage." He and Mr. Comber agree in supposing upwards of three millions to be in wheat. In barley, Mr. Young supposes nearly three millions; Mr. Comber, only one million; the latter estimate manifestly too small — the first probably too large. Both suppose about three millions in oats and beans.

1615. Attempts have been made to estimate *the value of the grain and cattle* reared in Great Britain; but these rest on such vague data, that they cannot be brought forward with any confidence.

1616. *Of minor articles of consumption we shall first mention hops.* By a report presented to parliament, the number of acres under cultivation for hops, in 1831, was 43,500, by far the greater proportion in Kent and Sussex, the rest in Worcestershire and Herefordshire. The average duty paid in 1829 and 1830 was 280,182*l.*, which, at 2*d.* per pound, showed an amount of 300,000 cwt., making, at 7*d.*, 2,100,000*l.* Cider. — The duty on cider in 1830 was 49,000*l.*, which, at 2½*d.* per gallon, makes 4,384,000 gallons, which, at 2*s.* each, amount to 438,000*l.*

1617. *Rape seed*, for the purpose of being converted into rape oil, which is much used in the coarser forms of the woollen manufacture. The quantity, raised chiefly in the counties of Cambridge, Essex, and Norfolk, was stated to parliament at 200,000 quarters, and the price at from 30*l.* to 40*l.* per last, making a value of about 700,000*l.*

1618. *The manufactures of Britain*, still more than even the immense products of her agriculture, have astonished the world, and raised her to a decided superiority over all other nations. This distinction she has attained, not so much by their extreme fineness; for, as to this particular, France excels not only in silks and cambrics, but even in woollens; and British porcelain does not equal that of Dresden. But she stands unrivalled in the immensity of useful and valuable products, calculated for the consumption of the great body of mankind; and above all in the stupendous exertions made in contriving and constructing the machinery by which they are produced.

1619. *The woollen manufacture* claims our first attention, as the old staple of the country. As soon as England began to exercise any kind of industry, her first aim was to manufacture her own wools, instead of leaving this operation in the hands of the Flemings. The fabric began in Kent and Sussex; but soon spread, and fixed itself in the interior districts; that of coarse woollens in the West Riding of Yorkshire, and that of the finer cloths in Gloucestershire and Wiltshire. In the end of the seventeenth century, its computed value was 8,000,000*l.* of which 3,000,000*l.* were exported. In 1800, from an enquiry instituted by parliament, the total value appeared to be 20,000,000*l.*, of which not much less than half was exported. In the course of the century, it has continued progressively increasing

though not with the same rapidity as some other fabrics. The introduction and remarkable extension of the manufacture of cotton has doubtless tended to check its growth. Though the quantity produced for internal use has greatly increased with the advance of population and wealth, the quantity exported has not been augmented in proportion. In the six years ending with 1789, the average had risen only to 3,500,000*l.* In 1802, it exceeded 7,000,000*l.*; but in 1831 and 1832 has been only 5,240,000*l.* This manufacture, however, depending chiefly upon home consumption, is less liable to vicissitude than those which have their principal market in foreign countries.

1620. *The wool*, which forms the material of this great manufacture, is partly produced in Britain, partly drawn from abroad. English wool is divided into long and short. The former being peculiar to this country, and long considered as exclusively adapted to worsted stuffs, bore a high value; but the recent improvements in machinery have enabled the manufacturer to produce these stuffs almost equally well from shorter wool. The short wool is fitted for cloth and hats; but all that is produced in England is of secondary fineness. Efforts were made about the close of the last century, especially by George III., to introduce the merino breed from Spain, and not without success; but the flesh, which in this country is the most valuable part, being in this species bad, and incapable of improvement, the farmers gave it up, and, devoting themselves to the improvement of the carcase, have allowed the wool even to degenerate, though the increased quantity is supposed to indemnify them. The best short wool is that of Sussex (Southdown) and Norfolk; the best long wool that of Lincoln. According to Messrs. Luccock and Hubbard, the number of short-woolled sheep throughout England, in 1828, amounted to about 14,850,000, that of long-woolled to 4,150,000; and the produce was 264,000 packs of long, and 120,000 packs of short wool; to which might be added 69,000 packs of lamb's wool, and 9000 for Wales; making in all 463,000. Wool, before it is used, must be *sorted*, or divided into parts of different quality. The best English wool is sorted into ten parts, of varying fineness. That formed into cloth is first carded, and after being spun and woven is subjected to the fulling mill, which gives it the proper consistence. The long wool, to be formed into worsted or stuff, is acted upon by red-hot iron combs, which bestow its peculiar texture. The defect of English wool renders it necessary to import a large quantity from abroad, which, after being discouraged for some time by a high duty, is now allowed at the rate of 2*d.* to 1*d.* per lb. The fleece chiefly valued is that of the merino, long confined to Spain: and Spanish wool, in the early part of this century, was introduced to the extent of 6,000,000 lbs. annually, but in 1827 it fell short of 4,000,000 lbs., and in 1832 did not exceed 2,626,000 lbs. It has been supplanted by the wool of Saxony, and other parts of northern Germany, where the merino breed has been introduced and propagated with the greatest success. The importation from Germany, which in 1810 was only 778,000 lbs., was in 1830 so high as 26,073,000 lbs., though in 1832 only 19,832,000 lbs.: New Holland and Van Diemen's Land in that year furnished 2,377,000 lbs. of very fine wool; and the supply is increasing. The entire import amounted in 1830 and 1831 to about 32,000,000 lbs.; in 1832 to only 28,140,000 lbs.

1621. *The entire produce of the woollen manufacture*, and the number of hands employed, has been variously and sometimes extravagantly estimated; but, by the judicious calculations of Stevenson and M'Culloch, their annual value appears to be 18,000,000*l.* or 20,000,000*l.* sterling, and the persons employed between 400,000 and 500,000. British woollens are exported to every quarter of the world, chiefly to Germany, to the value in 1832 of 816,000*l.*; Netherlands, 390,000*l.*; Russia, 144,000*l.*; Portugal, 96,000*l.*; Spain, 62,000*l.*; Gibraltar, 33,000*l.*; Italy, 194,000*l.*; France, 43,000*l.*; East Indies and China, 696,000*l.*; British America, 362,000*l.*; British West Indies, 93,000*l.*; Foreign ditto, 66,000*l.*; United States, 1,420,000*l.*; Brazil, 210,000*l.*; Mexico and States of South America, 437,000*l.* It was exported in the forms of 396,661 pieces cloth; 23,453 pieces napped coatings, duffels, &c.; 40,984 pieces kerseymeres; 34,874 pieces baize; 1,800,714 stuffs or worsted; 2,304,750 yards flannels; 1,681,840 yards blanketing; 690,042 yards carpeting; 133,072 yards woollen and cotton mixed; 152,810 dozens stockings. There were exported also 4,199,000 lbs. of British wool, and 2,204,000 lbs. woollen yarn.

1622. *The cotton manufacture* is of much more recent introduction. Although early mention is made of fustians, it appears proved that these were originally woollen imitations of the cotton stuff bearing that name. In 1641, however, a decided mention is made of cotton imported from the Levant through London, and not unfrequently sent abroad in a manufactured state. For a long period the progress of this branch of industry was slow. In 1705, the import was only 1,170,000 lbs.; about an hundredth part of the present amount. Even in 1760, Dr. Percival estimated the value of the fabric at only 200,000*l.* Soon after, an extraordinary excitement was raised in the minds of the persons connected with this manufacture, and machines of the most wonderful power were invented by common workmen. Cotton could not be spun in quantity sufficient to supply the looms. In 1767, James Hargreaves, a common Lancashire weaver, invented the spinning jenny, by which at first 8, and finally 120 spindles were moved by a single spinner. Hargreaves became exposed to the blind persecution of the working people employed in this operation; was obliged to flee to Nottingham; and, to the disgrace of the nation, died in poverty. Richard Arkwright, a barber of Nottingham, invented the water-twist, or "perpetual twist," spinning frame, in which the whole process was performed by the machine, and the workman had only to supply the material and watch its progress. Arkwright struggled with accumulated obstacles in his own ignorance of mechanism, the difficulty of procuring advances for the purposes of experiment, and the persecution of the mob; but at length he triumphed over all, and raised a large fortune by his invention. This frame, however, was not fitted for the finer manufactures. Mr. Samuel Crompton, in 1775, produced the machine called the *mule*, a combination of the two preceding, which soon superseded both in the finer and more valuable articles. Mr. Crompton did not take out a patent; but near the close of his life, more than thirty years after his invention had been carried into full effect, he applied to parliament for remuneration, when it was stated, that his machine set at work 4,000,000 spindles, employed 70,000 spinners, and 150,000 weavers; worked up 40,000,000 lbs. of cotton; and that the building and machinery connected with it had cost between 3,000,000*l.* and 4,000,000*l.* He received the miserable pittance of 5000*l.*

1623. *That machinery should weave as well as spin*, was necessary to consummate the triumph of art. This was accomplished by the Rev. Mr. Cartwright, a clergyman of Kent,

who, seeing a machine play chess, saw no reason why one might not also weave cloth. He accordingly invented one by which cloth was woven; but the first trial made at Doncaster was unsuccessful as to profit. The scheme was revived at Glasgow; and notwithstanding some abortive attempts, it made progress: but its introduction into Lancashire was slow and gradual. Two thousand power-loom, which existed in 1818, were reduced to one thousand in the following year; and an impression prevailed that cottons could be woven cheaper by the hand. Within the last few years, however, the system of power-loom weaving has been adopted to an immense extent; Mr. R. H. Greg estimates that there are in Britain 80,000, absorbing 10,000,000*l.* of fixed and 5,000,000*l.* of floating capital, employing 160,000 operatives, and working up 124,800,000 lbs. of cotton.

1624. *The steam-engine*, the moving power, the greatest of all these discoveries, remains to be mentioned. Machines moved by horses and water, originally employed in manufacturing and other processes, were cumbrous, expensive, and often unmanageable. The steam-engine, brought to perfection by Watt, became at once the moving power of all this machinery, and the principal cause to which its vast results may be attributed.

1625. *The cotton wool imported into Britain*, which in 1781 little exceeded 5,000,000 lbs., rose in 1792 to 35,000,000; in 1809, to 93,000,000; in 1817, to 126,000,000; in 1831, to 280,000,000; and in 1832, to 288,000,000. The finest is that called Sea Island, a name given to what is grown on the coast of Georgia and Carolina. The bowed Georgia, produced in the interior, is not of equal value. Next to the Sea Island rank the West India and Brazil. The common sort from the East Indies is the worst, and only used for coarse fabrics, and for mixing with other wool. Cotton of a peculiar quality, adapted for cambrics, is brought from the Isle of Bourbon and some parts of India. Mohammed Ali, pacha of Egypt, has of late years succeeded in raising a large quantity of excellent cotton. Of the quantity imported in 1831, there came from the United States, 219,333,000 lbs.; from Brazil, 31,695,000; from the East Indies, 25,805,000; from the West Indies, 2,401,000; and from Egypt, 7,714,000 lbs. The duty on printed cottons is now taken off; but it is supposed that their consumption has diminished in this country, silk being preferred as an ornamental dress, and the use of cotton, printed or dyed previously to weaving, having become prevalent. The demand abroad, however, is still extensive, so that the amount of pieces printed is about 4,500,000, giving employment to 100,000 persons.

1626. *The produce of the cotton manufacture* is estimated by Mr. M'Culloch, in the second edition of his *Dictionary of Commerce*, at 34,000,000*l.* annually. Of this he calculates that 18,000,000*l.* is paid in wages to 800,000 persons employed in its different branches; and that, allowing for those who are dependent upon them, and for the subsidiary employments, it will afford subsistence to not much fewer than 1,400,000 people. The value of cotton manufactures exported in 1831 was 13,282,000*l.*; of twist and yarn, 3,975,000*l.* Of these were exported to Russia, 1,960,634 yards; Sweden, 18,280; Norway, 434,744; Denmark, 312,461; Prussia, 1456; Germany, 41,520,616; the Netherlands, 13,285,524; France, 946,680; Portugal Proper, 23,377,245; Azores, 780,099; Madeira, 569,794; Spain and the Balearic Islands, 4,756,652; Canaries, 631,079; Gibraltar, 9,909,009; Italy and the Italian islands, 38,164,564; Malta, 1,967,953; Ionian Islands, 216,159; Turkey and Continental Greece, 24,565,580; Morea and Greek islands, 344,893; Egypt (ports on the Mediterranean), 2,354,628; Tripoli, Barbary, and Morocco, 7810; western coast of Africa, 2,384,000; Cape of Good Hope, 2,904,106; St. Helena, 73,371; Mauritius, 2,432,894; East India Company's territories, Ceylon, and China, 43,385,852; Sumatra, Java, and other islands of the Indian Seas, 5,915,088; Philippine Islands, 1,132,583; New South Wales, Van Diemen's Land, and Swan River, 1,905,428; New Zealand and South Sea Islands, 5014; British Northern colonies, 15,618,106; British West Indies, 21,975,459; Hayti, 6,828,576; Cuba and other Foreign West Indies, 11,569,441; United States of America, 68,587,893; States of Central and Southern America: viz. Mexico, 12,150,426; Columbia, 5,757,562; Brazil, 26,271,527; States of the Rio de la Plata, 6,242,134; Chili, 12,793,220; Peru, 6,312,931; Isles of Guernsey, Jersey, Alderney, Man, &c., 1,013,852. They were chiefly of the following descriptions:—Calicoes, cambric muslins, dimities, &c., 299,597,000 yards; lace, gauze net and crape, 48,164,000 yards; cotton and linen, mixed, 1,668,000 yards; velvets and velveteens, 404,000 yards; counterpanes and quilts, number, 23,000; hosiery, shawls, handkerchiefs, &c., 536,000 dozen; tapes, bobbins, &c., 99,000 dozen; thread, 1,105,000 lbs.; twist and yarn, 48,098,000 lbs.

1627. *The working in metals* is also one of the branches in which England has attained to a most decided pre-eminence. About the middle of the sixteenth century it rose to the rank of a staple; and within the last half century it has greatly increased in importance. Although it cannot rival the cotton manufacture either in its progress or its actual state, it has been marked by exertions of ingenuity scarcely less honourable to the persons employed. While the former branch of industry has displayed the wonderful power of machinery, the manufacture of hardware, dealing with more refractory materials, manifests especially the vast benefits resulting from the division of labour. In illustration of this principle, Smith had long ago remarked the multitude of persons employed in making a pin, and the marvellous dexterity thus acquired by each in this minute department. The manufacture of nails occupies nearly an equal number, and Mr. Warner mentions a species of knives, which, after passing through sixty different hands, were sold for twopence halfpenny apiece. Sheffield, perhaps the original seat of the trade in England, is still distinguished for the most solid and useful articles, knives, grates, and their appendages, agricultural implements, &c.; while Birmingham adds to these utensils a variety of small articles, ornaments, and toys, which, though minute in detail, amount to a vast value in the aggregate. Each of these two great cities forms, as it were, the centre of a large circle of population all employed in the same manner. That round Birmingham is particularly extensive; and Wolverhampton, Walsall, Dudley, and Kidderminster would be considered large manufacturing towns, were they not eclipsed by the proximity of so great a rival. The number of persons employed in the product and manufacture of metals is estimated at 350,000, and the entire produce at 17,000,000*l.* The export of hardware and cutlery in 1831 amounted to 16,799 tons, value 1,620,000*l.*; in 1832, it was 15,294 tons; value, 1,433,000*l.* Of this, 7874 tons went to the United States; 1549, British America; 1032, Asia; 1227, West Indies; 616, Mexico, &c.; 497, Brazil; 586, Germany; 229, Russia.

1628. *Other fabrics*, though on an inferior scale to those now considered as forming a chief source of the prosperity of Great Britain, and the basis of her foreign trade, contribute essentially to the welfare of her numerous population. The silk manufacture was of late origin in England; but it was considerably improved by the revocation of the edict of Nantes, which drove a number of French weavers into this country. It is established in a particular quarter of the metropolis, called Spitalfields, where it employs about 25,000 men: at Macclesfield, Manchester, Coventry, and in other parts of the country, the number occupied in it may amount to 40,000. Silks, after having been superseded to a great extent by cottons, came again into use among the rich, for whom cotton has become too cheap to serve the purpose of displaying wealth. The entire value of the manufacture was estimated some years ago at 4,000,000*l.*; and may now, probably, be between 5,000,000*l.* and 6,000,000*l.* Notwithstanding the removal of the prohibitory duties on the importation of foreign silks, the British manufacture has maintained its ground, and gone on increasing. While the average importation of raw and thrown silk in the five years ending 1818 was only 1,286,000 lbs., in 1832 it was 4,224,000 lbs.: of which 1,814,000 lbs. were from the East Indies and China; 1,006,000 lbs. from France; 564,000 lbs. from Italy; and 458,000 lbs. from Turkey. The exports amounted in 1832 to 525,000*l.* They were to all parts of the world, but chiefly North America and the West Indies.

1629. *In the manufacture of earthenware and porcelain*, England has of late made vast advances, and brought its various products to a high degree of beauty and elegance. Burslem in Staffordshire had, for centuries, been noted for its fabrication of a coarse kind of ware, which, in the last 200 years, was gradually extended; but it was reserved for Mr. Wedgwood to carry this art to perfection by a full combination of elegance and cheapness. Fine white clay from the south-western counties, and ground flint, are the chief materials of this celebrated ware, which bears the name of its inventor. Burslem, with Mr. Wedgwood's seat of Etruria, has now become the centre of a long range of villages, spread over a district which bears the name of the Potteries. The white ware of Derby and the porcelain of Worcester, though on a smaller scale, are still finer productions. The latter is composed of a mixture of 13 different materials, and each cup passes through 23 hands. Earthenware pays no duty, so that its amount cannot be officially ascertained; the export, however, has diminished from nearly 700,000*l.* in 1815-16, to only 490,000*l.* in 1832.

1630. *Although hides and leather* have never been ranked among the national staples, their amount must, notwithstanding, be very extensive. Hides are imported from all quarters of the world; the entire quantity in 1824 was 300,000 cwt., value 700,000*l.* Of these about one half were from Buenos Ayres and Monte Video; 24,000 cwt. from Brazil; 12,000 cwt. from Chili; 11,000 cwt. from the East Indies; 24,000 cwt. from Germany, and the same from Holland. In 1830 only 225,000 cwt. were imported. In that year the hides tanned or otherwise manufactured amounted to 46,800,000 lbs., which, at 1*s.* 8*d.* per lb., would be 3,900,000*l.*; and as the value of the finished article is supposed to be at least three times that of the material, this value will amount to nearly 12,000,000*l.* The shoes made in England are moderately estimated at 6,800,000*l.*, and Mr. McCulloch supposes that the whole manufacture employs at least 250,000 persons.

1631. *Beer, glass, soap, and candles* are branches of production which, though scarcely honoured with the title of manufactures, yet employ a large capital and numerous workmen, and yield a yearly amount of great value. In London the quantity of malt liquor annually brewed is 1,700,000 barrels, of which 38,000 are exported. This is chiefly *porter*, a liquor peculiarly appropriate to London, and for which she is famous throughout the world. All over England, there were brewed, in 1829, about 7,400,000 barrels. As the barrel of 32 gallons cannot be rated at less than 3*l.*, the produce of this great branch of industry must be upwards of 22,000,000*l.*; and this estimate does not include 1,500,000 barrels of table beer. *Candles*.—In 1829, the manufacture amounted to 110,000,000 lbs., which, at 7*d.* per pound, would make a value of 3,208,000*l.* *Soap*.—The manufacture, in 1829, was 100,000,000 lbs., which, at 7*d.*, would be 3,175,000*l.*

1632. *The linen manufacture* is that in which England is most deficient; for though she is supposed to produce the value of 1,000,000*l.* a year, this does not supersede the necessity of large imports from Scotland and Ireland. Of late, the elegant *manufacture of lace* has been carried to great perfection by means of bobbin net frames, invented in 1799, perfected by Mr. Heathcoat in 1809, and brought into general operation about 1820. By this manufacture a value of 160,000*l.* in silk and Sea Island cotton is wrought into lace, estimated, according to Mr. McCulloch, at 1,890,000*l.* and employing 208,000 persons. *Distilled liquors or spirits*, too, though they produce a revenue of 2,000,000*l.*, are neither equal in quality nor amount to those of the sister countries of Scotland and Ireland, whose produce, if it had not been excluded by national jealousy, would probably by this time have driven that of England out of the market. The quantity distilled in the two years 1831 and 1832 averaged 7,350,000 gallons.

1633. *Mines* form one of the most copious sources of the wealth of England. Those brilliant substances, indeed, which have been identified with wealth itself—gold, silver, diamonds, pearls—can be obtained only in exchange for the produce of her industry. But the substantially useful metals and minerals, those which afford the instruments of manufacture and are subservient to the daily purposes of life, are now drawn from the earth more copiously here than in any other country. Her most valuable metals are iron, copper, and tin; her principal minerals are coal and salt.

1634. *Iron*, the material of so important a class of manufacture, abounds in England, particularly in Wales, Staffordshire, and Derbyshire. While it was supposed, however, that the blast furnaces could be composed only of charcoal, the limited and always diminishing supply of wood depressed the produce, and even threatened to annihilate it. In the middle of the last century, the iron made in England from fifty new furnaces did not exceed 17,000 tons. It was then found, however, that, principally by the operation of the steam-engine, furnaces filled with coke might be heated to the same degree as those of charcoal, and the inexhaustible supply of coal might be employed in bringing the iron mines into value. Hence, in 1788, they yielded above 68,000 tons, of which three fourths were smelted in coke furnaces. The increased production has been astonishingly rapid. In 1796, it amounted to 125,000 tons; in 1806, to 250,000 tons; in 1820, to 690,000 tons. In 1830, it was still 680,000 tons; though the temporary depression of prices seemed to indicate that there had been some over-production. Pig iron, which, in 1824, brought from 12*l.* to 14*l.* a ton, had fallen, in 1831, to 4*l.* 10*s.* or 5*l.*; but it has now risen to 7*l.* 10*s.*; at which rate 680,000 tons will be worth 5,100,000*l.*; and which the additional labour of forming it into bar iron may raise to 6,300,000*l.* The export amounted in 1832 to about 150,000 tons, which, at the above rate, will be worth 1,120,000*l.* It is exported chiefly in the forms of bar iron, to the amount of 74,024 tons; bolt and rod iron, 6938; pig iron, 17,566; cast iron, 12,495; iron wire, 666; anchors and grapnels, 1606; hoops, 9417; nails, 4347; other kinds, 18,595; unwrought steel, 1112.

1635. *Copper*, also, has risen to importance in the course of the last half century. It is found chiefly in Cornwall, to the amount, in 1832, of 11,947 tons, and is carried thence to Swansea, to be smelted with the coal of North Wales, which itself produced 1320 tons of copper. That of Devon was 247 tons; Anglesey, 783; Staffordshire, 152; in all, 14,449 tons, which, at 90*l.* per ton, will be 1,300,410*l.*

The export, in 1832, was 77,497 cwt. unwrought, 79,944 cwt. in sheets, nails, &c., 37,170 cwt. in other states. It is sent chiefly to Asia, France, and the United States.

1636. *Tin*, a rare and peculiar metal, is found only in Cornwall and part of Devon. So early was it known, that we find the British Islands first recognised by its name, and it is enumerated among the articles with which the Carthaginians supplied the markets of Tyre. As Cornwall, with the exception of the Indian island of Banca, is the only tract known to produce tin in large quantities, there is a considerable export to most countries of Europe, particularly France and Italy. The produce of the mines in 1830 amounted to 83,044 cwt.; in 1831, to 81,622 cwt. The export in 1830 was 30,425 cwt., but in 1831 fell to 21,762 cwt. In 1827 it had been so high as 49,474 cwt. The cwt. may be valued at 3*l.* 16*s.*, which in the first year made the total value about 115,000*l.*; in the second year, 82,520*l.* The year 1830, however, may be most properly taken as a general average.

1637. *Lead* is found in Cumberland, Derbyshire, and Northumberland, to the supposed amount of about 16,000 tons annually; which, at 20*l.* per ton, will be worth 320,000*l.* In the year ending the 5th of January, 1833, the British lead exported was 13,898 tons, value 277,960*l.* There had been imported 1386 tons, of which 978 were re-exported.

1638. *Coal* is the most valuable of all the mineral substances from which Britain derives her prosperity. This precious product, which exists in almost inexhaustible quantities in the counties of Northumberland, Derby, and Stafford, and in that of Glamorgan in South Wales, may be regarded as the main support of the whole system of British production. It fuses the metals, produces the steam which sets the machinery in motion, and is, indeed, instrumental in bringing almost every substance into a useful and merchantable form. By superseding also the necessity of extensive plantations for fuel, it enables a much greater proportion of the soil to be devoted to cultivation. The Northumberland and Durham field has been estimated at 732 square miles, the South Wales field at 1200; which, allowing for the average depth, will, it is calculated, be sufficient to supply all England for 1700 or 2000 years. At all events, it seems certain that she is secure for many centuries against any deficiency. The quantity shipped from Durham and Northumberland is stated by Mr. Taylor at 3,300,000 tons; and he estimates the whole employed as fuel, and in the manufactories and mines throughout England (adding 700,000 exported to Ireland), at not less than 15,500,000 tons. The mines on the Tyne employ 8491 persons underground, and 3463 above; those on the Wear, about three fourths of this number: the conveyance of these coastwise employs 1400 vessels and 15,000 men; while, in London, 7500 whippers, lightermen, factors, agents, &c. are engaged in landing and distributing it. Adding these together, and taking into view the whole of Great Britain, Mr. M'Culloch considers that the coal trade will give occupation to not less than 160,000 persons. The oppressive and unequal tax on coal imported into London has now been removed. In 1829, the total quantity shipped was 6,224,125 tons; of which, 5,014,132 were sent coastwise; 840,246, to Ireland; 128,893, to the British colonies; 356,419, to foreign countries. The export is chiefly to the Netherlands, Germany, Denmark, British America, and the United States. The imports into London, in 1832, amounted to 2,149,820 tons, brought by 7528 vessels.

1639. *Of salt*, an indispensable necessary of life, and an article of essential use in the fisheries, Britain fortunately possesses an immense supply. Her stores of coal would enable her to procure it to any extent from sea-water; but the finest and most valuable kind is the rock salt found at Northwich and Middlewich, in the county of Chester. It is drawn from mines and from brine springs, both of which were discovered only a hundred and forty years ago, on the estate of Mr. Marbury. As these were worked, new veins were always traced, till the abundance proved such, as to remove all alarm of exhaustion. The salt, at first coarse, and of the colour of sugar-candy, is refined by being boiled along with the brine of the springs, and is then called white salt. Till of late, rock salt was burdened with the enormous duty of 15*s.* a bushel; and though it was allowed duty free for the fisheries, yet the restrictions attending the exemption greatly fettered this branch of industry. The repeal of the duty was, very judiciously, one of the first measures of economy after the peace. While the tax was in operation, the produce of the Cheshire salt mines was found to be about 10,000,000 bushels, of which upwards of 8,000,000 were exported to foreign parts, 1,000,000 was allowed duty free for the fisheries, and less than 1,000,000 paid duty. Mr. M'Culloch estimates the present produce at 15,000,000 bushels, of which about 10,000,000 are exported, chiefly to North America, the Netherlands, and Russia.

1640. *Good stone for building* is not to be found in many parts of England. The Portland and the Bath stone are the finest. Almost all her cities are built of brick; and the duty of 466,000*l.* paid for bricks in the year 1824, shows the extent and value of this material.

1641. *The commerce of Britain*, like her manufacturing industry, is now completely without a rival. Tyre and Carthage, in their greatest glory, when commerce gave them a power equal to that of kingdoms, possessed, probably, but a small proportion of that which circulates through England both within and without. Her exports and her imports, and her internal trade, are all on a scale of equal magnitude.

1642. *The exports of Britain* consist almost wholly of her manufactured produce; for grain and other parts of the produce of land have been prevented only by prohibition from being largely introduced from abroad; and, even when the home price was complained of as not sufficient to remunerate the grower, it was still better than any that could be obtained on the Continent. As to manufactures, so far as foreign demand is concerned, those of cotton have more and more taken the precedence of all others. In 1830, the quantity exported, including twist and yarn, was valued at above 15,000,000*l.* sterling; being two

fifths of the whole exportation. They are sent to every country, but most especially to those from which the raw material is imported. The United States take an immense quantity; the West Indies and Brazil import largely; and the market in the independent states of South America is daily enlarging. In 1824, cotton goods, exceeding 3,000,000*l.* in value, were sent thither from Liverpool alone; and they make their way in increasing quantities even into the East Indies. In Europe, Portugal and Italy are extensive markets; and though studiously excluded from Spain, large consignments are sent to Gibraltar, evidently with a view to clandestine introduction. Germany takes a great quantity both of manufactured goods, and of yarn and twist for her own manufactories. The fabric is not suited to the north of Europe; and from France it is in a great measure excluded by dint of prohibition. The woollen manufacture has a different and less extensive range. The United States, still the greatest market, take three eighths of the whole; after which rank the East Indies, Russia, Portugal, and Germany. The wrought metals find a great variety of markets. Of bar iron, 7000 tons, and copper 50,000 tons, go to the East Indies. Ireland takes 7000 tons of bar, 700 of cast, and 2300 of wrought iron. The West Indies take largely both iron and copper.

1643. *The following Table exhibits the amount of the leading articles of exports, according to their declared or real value, during the three years ending 5th January —*

ARTICLES.	1829.	1830.	1831.
	£	£	£
Apparel	423,000	390,000	387,000
Arms and Ammunition	335,000	279,000	241,000
Beef and Pork	142,000	208,000	195,000
Beer and Ale	245,000	249,000	212,000
Books printed	102,000	109,000	94,000
Brass and Copper Manufactures	678,000	810,000	864,000
Butter and Cheese	352,000	293,000	263,000
Coals	145,000	147,000	184,000
Cotton Manufactures	13,649,000	13,558,000	15,294,000
Cotton Yarn	3,595,000	3,976,000	4,133,000
Earthenware	502,000	463,000	441,000
Fish	242,000	186,000	246,000
Glass	501,000	475,000	401,000
Haberdashery, &c.	486,000	395,000	385,000
Hardware and Cutlery	1,387,000	1,390,000	1,412,000
Hats	220,000	205,000	225,000
Iron and Steel wrought and unwrought	1,229,000	1,157,000	1,078,000
Lead and Shot	177,000	114,000	106,000
Leather, Saddlery, &c.	363,000	351,000	335,000
Linen Manufactures	2,180,000	1,888,000	2,061,000
Machinery	262,000	250,000	208,000
Painters' Colours	138,000	131,000	100,000
Plate and Jewellery	181,000	177,000	190,000
Salt	154,000	174,000	183,000
Silk Manufactures	255,000	267,000	521,000
Soap and Candles	268,000	227,000	246,000
Stationery	207,000	190,000	171,000
Sugar, refined	1,038,000	984,000	1,288,000
Tin	147,000	120,000	106,000
Tin and Pewter Wares, &c.	266,000	235,000	249,000
Whalebone	63,000	40,000	41,000
Woollen Manufactures	5,125,000	4,661,000	4,850,000

1644. *Among our imports*, a large proportion consists of raw materials, brought in vast quantities to be manufactured, in many instances for the use of the regions from which they come. Under the head of manufactures, we have enumerated the principal of these articles, and the countries from whence imported. They are chiefly cotton, wool, silk, and hides; to which may be added, bark, ashes, and barilla; cochineal, indigo, madder, and other dyeing stuffs. Although grain and provisions are now produced in sufficient quantity for internal consumption, there is much want of the raw produce of uncultivated land. Under this head a prominent rank may be assigned to timber and naval stores; on which, however, Britain has adopted the rather unaccountable policy of laying a heavy duty (made much heavier on those brought from the Baltic, which are by far the best), with the injudicious view of giving a monopoly to our North American colonies. A liberal commercial spirit, however, has lately made great progress towards an equalisation of these duties. Fir and oak timber, and staves, are brought chiefly from North America; masts, deals, and deal ends, from Norway and Russia; oak plank from Prussia.

1645. *The import trade* of consumption is, after all, the most extensive: it consists chiefly in obtaining from southern regions, and those warmed by tropical suns, the accommodations and luxuries which cannot be matured under our less genial sky. Wine, the most delicate and wholesome of fermented liquors, would have been introduced to a very great extent, had not its exclusion been made a prime object of fiscal regulation. This, however, has been so potently applied, that the use of wine has not increased in any proportion to the general wealth of the nation; and it has been forced from the nearest and best wines of France, to the less palatable produce of Spain and Portugal. The following is a view of the wine trade since 1700 (in tuns): —

Date.	Portugal.	Madeira.	Spanish.	French.	Rhenish.	Total.
1700	7,757		13,649	664	1,430	23,520
1750	9,050		5,714	418	272	15,454
1790	21,431	1,464	5,008	1,101	122	29,146
1810	27,360	2,350	11,732	4,117	133	45,692
1814	15,498	2,018	7,674	3,905	126	29,221
1830	11,638	905	8,543	1,338	283	22,707

To the last year however, must be added 2130 tuns of Cape wine, 429 Canary and Fayal, 1030 Sicilian : in all 26,296 tuns.

1646. *The value of wine imported in the last year is stated at 791,739*l.*, producing, however, a revenue of 1,524,177*l.* Brandy, also, still accounted the finest of spirituous liquors, forces itself to a certain extent, into the circle of our imports. But the saccharine and aromatic products of the tropical plains are those for which our climates can yield no substitute. They form the basis of an immense commerce, which even the adherents of the mercantile system cherish, under the idea that much of it is carried on with our own colonies. The leading articles are sugar, tea, coffee, tobacco, and spices. Notwithstanding the immense cotton manufacture of Britain, the piece goods of India, by their peculiar excellence, still found their way in that year to the extent of 410,000*l.* Cinnamon, 133,000*l.*; pepper, 47,000*l.*; cloves, 39,500*l.*; nutmegs, 49,500*l.*; mace, 9,800*l.**

1647. *The following Table exhibits the amount of the leading articles of import in the three years ending 5th January —*

IMPORTS.	1829.	1830.	1831.	Re-exported 1831.
	£	£	£	£
Almonds	40,000	19,000	30,000	
Ashes	203,000	212,000	306,000	10,500
Barilla	167,000	128,000	212,000	2,800
Bark	178,000	217,000	216,000	
Brimstone	153,000	160,000	130,000	
Butter	278,000	203,000	149,000	
Cheese	314,000	244,000	157,000	
Cinnamon	67,000	108,000	92,000	133,000
Cloves	121,000	9,000	39,000	14,800
Cochineal	207,000	231,000	255,000	113,000
Coffee	2,534,000	2,395,000	2,559,000	1,255,000
Cork	52,000	49,000	37,000	
Corn	1,673,000	3,510,000	3,279,000	136,000
Cotton Manufactures of India	344,000	505,000	410,000	590,000
Cotton Wool	7,550,000	7,343,000	8,785,000	718,000
Currants	172,000	125,000	19,000	10,000
Elephants' Teeth	21,000	25,000	32,000	
Cod-fish	113,000	122,000	82,000	42,000
Flax and Tow	1,781,000	1,875,000	1,911,000	7,000
Furs	175,000	184,000	156,000	
Gums	105,000	108,000	91,000	
Hemp	424,000	302,000	394,000	12,000
Hides	660,000	846,000	992,000	162,000
Indigo	1,349,000	876,000	1,121,000	898,000
Iron, in bars	153,000	156,000	152,000	38,000

1650. *The shipping by which so extensive a trade is carried on, must necessarily be very extensive. The number of vessels belonging to the different ports in England was returned, on the 31st December 1825, 1826, and 1827, at the average of 22,363; their tonnage, at 2,421,224 tons. An immense progress, however, is exhibited since 1663, when it was only 95,000 tons. It rose in 1701 to 273,000; in 1751, to 609,000; in 1774, to 901,000; in 1792, to 1,186,000. The number of ships built in these last years is not*

inconsiderable: in 1822, 442 ships, 43,212 tons; in 1824, 625 ships, 76,428 tons; in 1827, 650 ships, 72,065 tons; in 1832, 708 ships, 88,271 tons. The vessels belonging to the British empire at the end of 1832 were 24,485, of 2,618,068 tons, and navigated by 161,634 men. The entries and clearances for the coasting trade, amounted each to 8,500,000 tons. Besides these, in the same year, 4546 foreign vessels, comprising 639,979 tons, and navigated by 35,399 men, entered the ports of Great Britain.

1651. *The following is the amount of the tonnage employed in the trade with the different countries of the globe, in the year 1832: —*

Countries.	Inwards.		Outwards.	
	British.	Foreign.	British.	Foreign.
Russia - - - - -	277,527	32,132	202,610	24,978
Sweden - - - - -	8,835	25,755	9,660	13,403
Norway - - - - -	3,798	82,155	3,411	86,540
Denmark - - - - -	7,268	35,772	65,658	70,413
Prussia - - - - -	62,079	84,187	41,027	70,252
Germany - - - - -	130,443	31,087	121,872	37,247
Netherlands - - - - -	195,473	90,492	176,741	88,059
France - - - - -	110,793	63,500	116,688	50,161

1652. *The fisheries do not seem to have been so much cultivated in Britain, as the hardy enterprise of the nation might have led us to expect. The Dutch were allowed for a long period to carry off the produce of the rich banks surrounding the British Islands. Of late, the attention of the nation has been more and more directed to this object. The whale fishery has been pursued to a great extent; and it was considered so valuable, both for its products, and as a nursery for seamen, that, till 1824, a bounty was granted in proportion to the tonnage of the vessels employed. They have found their way to the antarctic polar sea, in search of an oil which, though not superior for burning, is better adapted to the purposes of manufacture, than that drawn from the arctic regions. This fishery, within the last twelve years, has considerably diminished both in amount and in the value of its products, partly owing to the use of gas, the greater cheapness of rape-oil for manufacture, also to a larger part of the trade being engrossed by Scotland. In several years, ending with 1818, there were employed, on an average, 92 vessels, that, with 40 from Scotland, brought in 13,788 tuns of oil, and 684 tons of whalebone; which, valuing the former at 36*l.* 10*s.* and the latter at 90*l.*, produced an annual value of 566,722*l.* In 1829 and 1830, there sailed from England only 41 vessels, of 13,766 tons burden; which, in 1829, brought in 420 whales, yielding 4912 tuns of oil, and 289 tons of whalebone. The oil could be then valued only at 25*l.*, but the bone had risen to 180*l.*; consequently, the entire produce might be estimated at 174,820*l.* The following year was still more deficient, owing to the disasters encountered by the vessels engaged in the fishery. The building of each of these vessels costs about 8000*l.*, the annual outfit is 3000*l.*; while the warehouses and machinery may be worth 100,000*l.*; making in all a capital of 551,000*l.* invested in the trade. The produce of the southern fishery in 1829 appears to have exceeded 50,000*l.**

1653. *Of the fisheries in the British seas, that of Herrings, the most important, belongs almost entirely to Scotland. Next to this ranks that of Pilchards, on the coast of Cornwall and part of Devon. The fish is found there in such immense shoals, that it forms the chief food of the people during the greater part of the year, and is also largely salted for exportation. The value annually taken is reckoned at 50,000*l.* or 60,000*l.* Considerable activity is used in these counties in taking pilchards for immediate consumption. Similar exertions are not made elsewhere in England, unless at the mouth of the Thames, and on the coast of Suffolk, where a considerable number of vessels, fitted with wells and other apparatus, convey to the capital a great quantity of excellent fish in perfect preservation; but the price is too high to bring it within reach of the great body of the citizens. Essex has likewise a valuable oyster fishery, producing 14,000 or 15,000 bushels. In 1812, an*

association was formed for the improvement of the fisheries, from whose exertions considerable hopes are entertained for this hitherto neglected branch of British industry.
